But besides this, I must also state that I independently invented, and described in a letter to Sir Baldwin Walker in 1857, the whole system of floating cylinder with all attachments. I was then serving in Brazil, and had never heard anything of Mr. Lavater, whose acquaintance I first made soon after my arrival in England in 1858, when, on seeking provisional protection, I was informed of the existence of Mr. Lavater's invention. I at once communicated with him, and I have his letters still. We agreed to take out the patent together; but circumstances occurred which induced him to give up any further share in the enterprise. Since then I have consistently advocated the system as the cheapest and safest, as well as the most seamanlike, method of laying cables in the state in which the makers left them; and Mr. Lavater before we parted expressed himself perfectly satisfied that the cylinder alone would have had little value without the modifications which only a seaman could be expected to foresee as necessary.

I hope that the contemplated laying of an Atlantic cable by means of the Great Eastern may prove a success, for I am confident that the cheapest and best means of laying will eventually be brought into use; and I do not think that we shall ever build as many Great Easterns as I trust we shall lay deep-sea cables. A failure would be the worst possible occurrence for all parties, as not only would shareholders lose their money, but telegraphic progress would receive a "heavy blow and great discouragement."

But I cannot say I am sanguine that this success is certain, for I see that the time occupied in laying must be doubled, and therefore the chances of a fatal gale of wind must be increased; that the cable is proportionately lighter than its predecessor, and therefore exposes a greater area to cross currents on the surface; and that, though the Great Eastern may pitch less, she rolls worse, and will "*scend*" or travel forward with the wave more in proportion as she is longer than former vessels. These are added difficulties where already there were enough; and if we join to this that in spite of all the lessons already received, a spiral system of outer wires is still adhered to, bedded in a material even softer than gutta-percha, as hemp, a system which adds weight without contributing one iota to strength quoad the conductor, I fear much that we have no right to look for success or to hope that we shall avoid failure.

Even now this element of strength which the "happy accident" of the Persian Gulf cable should teach us is wholly wanting in spiral wire covered cables, might be supplied to the Atlantic by the use of straight steel wires embedded in macintoshes—not Bright and Clark's—compound macintoshes having the great advantage of being flexible and easily put on cold, while Clark's is brittle, and must be put on hot, or at least warm.

I am quite sure that no precaution will prevent (with the asphalte coating) rapid decay of the iron sheathing at hundreds of points where it will be rubbed or cracked off during the laying; and if, as some say, it is no matter how soon the outer wire decays after the cable is down, what, in the name of common sense, is the use of the iron sheathing at all? As for protection from mechanical violence during the multifarious coilings back and forth, the best remedy for that seems to be an inquiry whether such treatment is necessary or no, and I think there are now very few believers in the foolish idea that the wires form an arch, and therefore cannot extend, so that I do not anticipate finding any advocate for their use in giving strength as far as preventing the rupture of the conductor is concerned. I propose at the coming meeting of the British Association to go into the question of submarine telegraphy, and I hope that scientific inquiry may then be able to establish facts of which I have myself long been convinced, namely, that cables can be made at half the price now considered necessary, with a far better insulator than either gutta-percha or india-rubber, and one which at the same time has much less inductive capacity; also that cables can be laid without difficulty if seamen be allowed to decide the route and the means to be adopted, and be not, as heretofore, only grudgingly called in, when the wrong way has been tried and failed, to have their opinions stolen and misused by those who would unjustly reap the rich harvest of rewards, a harvest of which only professional skill can either sow the seed or deserve the return.—I remain, yours truly,

London, August 23rd, 1864. J. H. Selwyn, Capt. R.N.

[We have forwarded the pamphlet to our correspondent. Captain Selwyn's explanation is most satisfactory.—Ed. *T. J.*]

INDIA-RUBBER CABLES.

To the Editor of the Telegraphic Journal.

Sir,—Despite all that Mr. Henley may say, gutta-percha insulation for long deep-sea cables is a prodigious failure, and to go on using it is only to increase the magnitude of the blunder. Now, no one regrets this more than the advocates of india-rubber; and I again assert that this has had more to do with keeping rubber out of the field than any other cause. Where the "strangeness" of the assertion can be I am at a loss to comprehend. Shall I insult the discernment of your readers by explaining how? Suppose the Atlantic cable, the Red Sea cable, and other important long lines that have failed, had been successful, should we not have had some 40,000 or 50,000 miles of long deep-sea telegraphs ere this? And would it not have taxed the combined efforts of both gutta-percha and india-rubber men to supply the demand? Then there would have been a "fair field and no favour;" both materials would have been tried on the same vast scale, and men like Mr. Henley would then have been able to have written about rubber with the same glib familiarity as they do about percha: whereas, it were wise now if they would refrain from condemning a material they know nothing about. But, alas! it is not so. We have no long cable; all have come to grief; and the ones promised are looked upon as hazardous experiments, the success of which will disappoint the world more than their failure. For the sake of the tax-paying public, the Atlantic telegraph shareholders, and the firms who have embarked large capital in both gutta-percha and india-rubber, I do fervently hope that we may be most agreeably disappointed in this way, and that the former material may prove to us indubitably that it is not a prodigious failure. At present, however, that is the verdict, nor can Mr. Henley or any one else show that it is not so.

Referring to his first letter, Mr. Henley says, "My only object was to vindicate myself from misstatements," &c. What a pity he did not confine himself to this. Certainly the comparative merits of the two insulators is a subject not necessarily wrapped up in it.

Mr. Henley is a man who has risen from the ranks: so much the more to his honour. He is, I believe, generally esteemed as second to none in his

trade or profession, or whatever it may be termed, and, having been a working man, he is, of course, a practical man; and certainly in telegraph operations we could do very well with a few more such men; but then his letters prove him to be characterized by more than all the dogmatism, self-sufficiency, and exclusiveness of his class—a class who peculiarly abound in bounce, by which the detraction of others serves to set off themselves. There is more "buncombe" in these two letters than I have seen in any other two out of the domains of President Lincoln. Of course he can make 20 miles of cable a day—why not? or 200 perhaps? It is immaterial which while you are about it; the generality of people care very little about these things; but it is hardly seemly to say, "Oh, I don't believe so-and-so have done such a thing, or can do it," and a great deal of the same sort, which could have nothing to do with the subject, and, withal, is far from being gentlemanly. He should go back a few years, and compare notes; but this is a disagreeable strain, and I can only regret your correspondent should have led me into it.

Mr. Henley thinks well to contradict me in a few minor matters: it is perfectly immaterial. He is referring to the present. I was speaking in the past tense. I am truly pleased his facilities for cable manufacture are so effective. I like to hear of a man getting on; but it betrays a pettiness of disposition unbecoming any man to be so complacently self-satisfied of his own position while disingenuously trying to injure another's.

Your correspondent says, "Gutta-percha needs no puffing." Well, that's a good joke at any rate. Mr. Henley himself has puffed it enough to last a twelvemonth; in fact, according to another correspondent, he has puffed it up to such an extent that the other has vanished completely from the field; "its days are over," so let us sing its requiem.

Gutta-percha never fails, certainly not. But what becomes of it "when suspended in air?" It never "shrivels up," I suppose, nor "peels off," nor goes to dust? And of course it never goes bad out of sight. We are all good people when no one sees us, or can know to the contrary; but I could show Mr. Henley a gutta-percha wire, the insulation of which was no better than so much rotten cheese after four years' submersion; but this would be superfluous; you know the distich, and that will save me the trouble of quoting it.

"Hit a man when he's down," that is the way of the world, and therefore it is sound philosophy. It is assumed that india-rubber is come to grief, and so Mr. Henley hammers away like a good old Anglo-Saxon. Well, well, we know who pulls the strings; but wait a bit; it is quite premature to give the finishing stroke yet. It is a dummy you are belabouring all the while, I fear. Candidly, I think you'll find the real antagonist worthy of you. It will come forth as a giant refreshed by-and-bye. But what has led to all this hubbub of valiant knights coming forth to do battle? Verily, a ruse or a scarecrow. More will be known shortly. At the present a report is set afloat. What is it worth? What is the ostensible motive for putting it forth? Simply as a sort of stalking-horse to divert attention from something far more serious: what that is I need not say. It causes nervousness in certain quarters lest that should certainly result which has been prognosticated over and over again, and which some persons in high quarters have been expecting all along; and so this allegation will serve as a set-off.

A word or two with "R. Watson," the little echo of Mr. H. You are mistaken, sir, if you imagine I "plead for the manufacturer," or any one else. I think the manufacturers were very foolish for having anything to do with the making of the cable if they were not allowed to make it on their own patent; and I said as much before. I presume these gentlemen are competent to plead for themselves if they find it necessary; they are acting wisely, however, in treating the absurd nonsense that has been written with silent contempt.

You speak of a "defunct india-rubber cable in the Persian Gulf." Upon my word, sir, you must be a well-informed individual—far more so than even Colonel Stewart.

Can I "bring forward a single instance in which india-rubber has succeeded?" Why, my verdant friend, india-rubber never fails, "if properly treated." (Mr. Henley uses the qualifying "if" with the immaculate, and surely I may be allowed). The mischief of it is it *never has been properly treated* in the few instances in which it has been tried for submarine cables: and I deny in toto that it ever turns to treacle in sea or in earth when manipulated in a certain way, and I could produce a dozen instances in proof of it.

I am obliged for Mr. Henley's advice. In reply he will give me leave to say that I opine it would be more to his and others' credit if they were to give this matter a fair and dispassionate consideration, instead of "bolstering up" a monopoly which weighs like an incubus on the neck of a young science, and in which our bungling and blundering has made us the laughing-stock of the world. But what does this matter so long as monopoly and its parasites can fatten upon the spoils of the credulous? If we go on as we have commenced, submarine telegraphy will engulph more hard cash than was lost in the South Sea bubble, and hitherto it has been about as safe a speculation; and it certainly promises no great things for the future, when those who are striving to make it a safe one are hooted out of the field.

Because of the alleged failure, or partial failure, of twenty miles of india-rubber cable, there is a hullabaloo set up, as though this metropolis were on fire; but there is a comparatively dead silence when thousands upon thousands of miles of gutta-percha cable give up the ghost and become useless, and none but the fates, and perhaps one or two officials, have any conception of the huge heaps of useless wire of the same sort that year by year accumulate in the storeyards of the various telegraph companies. Altogether, this fierce onslaught of sleek monopoly is as unseemly as it is futile, and, as it will ultimately prove, uncalled-for.

With significant inconsistency Mr. Henley shirks the main thing. I may get the percentage of a workable cable myself. It would damage his cause and the cause of those he serves to do so. Probably I shall take an early opportunity of doing so, and then, sir, your readers may judge for themselves of the value of Mr. Henley's eulogiums. Mr. H. may have the last word if he choose. I have nothing further to say to him. Beppo.

THE TELEGRAPH CLERKS' FUND.

To the Editor of the Telegraphic Journal.

Sir,—I read with great pleasure the account of the soirée and conversazione given by the above excellent institution on the 8th inst. What pleased me most was the novelty of a telegraph company Director being present. I agree with you that great credit is due to Mr. Sheward for attending a meeting of the kind, the object being so praiseworthy. It is painful to think that telegraph directors, and those put in high authority under them, do not evince the least interest for the welfare of their employés generally; in fact, I was informed the other day that in one or two large establishments the "servants did not know their masters even by sight." I hail with satisfaction the efforts of the employés to foster that kindly feeling among themselves which certainly does not exist between the directors of their respective companies.—Yours obediently, A Shareholder.

TELEGRAPHIC NEWS.

Time Gun.—At the last sitting of the River Tyne Commissioners the Dredging and River Works Committee reported that a letter had been received from the solicitor of the Electric Telegraph Company, on the subject of the agreement between the company and the commissioners for the transmission of the electric current from Greenwich to fire the time guns at Newcastle and Shields.

Marine Signals for all Nations.—The French Minister of Marine has made a report to the Emperor in relation to the establishment of a universal code of maritime signals, which will offer to all nations a uniform means of communicating at sea, and with lighthouses on the sea-coast. The Emperor, upon receiving the report, issued a decree, in which he states the commercial code of signals for all nations—such as has been adopted by the Anglo-French Commission—shall be the only one employed for the interchange of communication by French vessels, either among themselves and with semaphores on shore, or with the vessels of other nations. This is very important to mariners, and the vessels of the United States should immediately procure the flags and books.

The Atlantic Cable.—We see it stated that Mr. Cyrus W. Field has sailed in her Britannic Majesty's steamer Margaretta Stephenson for Trinity Bay, with the purpose of selecting a place for the landing of the Atlantic telegraph cable. This would prove that this long-promised and eagerly-expected communication between the Old World and the New may be realized ere long. It is stated in the London journals that the new cable is of so superior a make that it may be confidently expected it will not break. This cable, if successfully laid, will revolutionise many things. It will undoubtedly tend to promote good-will between us and the European communities, and will prevent those misrepresentations which so frequently lead to national difficultes. A French company, or rather a project of a company, for laying an ocean cable between France and this country has been started in Paris; but unless the line from England be successful this will never be undertaken. The purpose of the French company is to form an opposition or competition, in case it is proved that a line may be worked. Messrs. Rowett and Troltes, the parties who represent the French company, have been ventilating the thing for years; but no attention was paid to them by the French Government until it became apparent that one more trial would be made by the original Atlantic Telegraph Company; then the Emperor Napoleon ordered his Minister of the Interior to grant to Messrs. Rowett and Troltes a concession for connecting the islands of St. Pierre and Miguelon with France by an ocean cable. The interest of the world at large will, of course, be served by having two cables, and in case of the success of the first the second will unquestionably be laid.

The Overland Telegraph to Russia.—Amid the bustle of war a work of peace and civilization has been steadily growing. The telegraphic project to unite the United States and Russia has entered into the stage of real work; the last impediments have been overcome, and now Mr. Collins, conjointly with the Western Union Telegraph Company, has already begun the work. Four ships have been chartered and freighted with the telegraphic wire, implements, provisions, tents, &c., and will soon start for San Francisco, sailing round Cape Horn. This fall the fleet will reach San Francisco. The Government of the United States has detailed a man-of-war for the purpose of helping the company. Four exploring parties will be left respectively at New Westminster, Fraser river; Point Desolation, on the line between British and Russian America; Sithka, the capital of

Russian America; and at Cook's Inlet. These parties are to explore the coast; if possible, obtain all the timber wanted; and prepare the ground for next spring's work. Mr. Collins hopes that in two years from autumn the two continents will be united. The capital of ten millions of dollars for this transcontinental line has been subscribed in the United States; and the Russian Government builds on its own account the line from Petersburg to Nikolaef, on the Amoor. The line has already reached Chita, a town situated at the confluence of the Shilka and Erlon, the beginning of the Amoor.—*New York World.*

Anglo-Indian Telegraph.—The insurrection of the Montefic Arabs is now entirely quelled, and the state of the disturbed district between Diwanyeh and Korneh is now such that the telegraphic works can be resumed, but it will not be possible to make much progress until the autumn, as the men can do very little work during the present hot and unhealthy season. Colonel Goldsmidt arrived at Mosul (the site of the ancient city of Nineveh) early last month, on his way to Constantinople, to report on the condition of the line through Asia Minor. He will then meet Colonel Stewart, C.B., who left Bombay by the mail of the 24th June. It is earnestly to be hoped that strenuous exertions will be made by the Government to provide a proper service of English Clerks at the chief stations between Scutari and Fao, without which it is utterly impossible that the enormous commercial traffic which may be looked for directly the Anglo-Indian line is opened can be efficiently performed. The technical character of the messages between merchants in England and India, the quotation of prices of various kinds of stock and goods, the names of vessels, and many other details which will naturally occur to any one accustomed to the daily routine of a telegraphic instrument room, will otherwise be so mangled in transmission as to render the line more an agent of confusion than of utility, and the result of a bad beginning will retard the advance of the traffic afterwards more than the Turkish Government (who are so largely interested in obtaining good returns) can probably receive. By far the greater part of the messages will be in the English language; and it is absurd to suppose that any Turkish official, however much he may have studied it, can master the names and expressions of mercantile dealings sufficiently to cope with the business in a satisfactory manner. The Persian line between Teheran, Ispahan, Shiraz, and Bushire, is proceeding rapidly, and will most likely be (in connection with the Russian line *viâ* Tiflis and Tabriz) the first by which the Persian Gulf cable is worked through to India.—*Malta Observer.*

Singular Accident from Lightning.—The following interesting account of a meteorological accident at Dachute has been communicated to us (*Montreal Herald*) by a friend, to whom the letter containing it was addressed:—"We met with rather a serious accident from lightning on Monday last; but we have reason to thank God we escaped so comparatively unscathed. Between two and three o'clock our house was struck. The crash was terrific. The electric current penetrated the building, struck the bell-wire, and ran along it in both directions—the one current ran along the wire into the interior of the building, until it passed into the cellar where it escaped into the ground, and ignited my surgery floor in its course; the other current followed the other extremity of the wire, and passed through the bell-pull and struck one of my children, a little boy of nearly four years of age. The fluid ran down the left side of his head and face, burning the hair and discolouring the skin, and along the chest and inside of the arm, and escaped into the ground tearing up the floor in its passage. After a short time the whole of the left side of the chest and inner side of the arm became covered with livid veneations. The child appeared to be dying for some time, but gradually recovered. The cold effusion appeared to be beneficial in restoring animation. He lay unconscious for a considerable length of time, and after recovering he vomited at intervals for nearly twenty-four hours. He appears to be out of danger now, but suffers severely from the extensive blistered surface. The building is perforated in several places about the size of a musket-ball, and blackened as if charred with gunpowder; but otherwise is not much injured. The bell-wire was fused, and dropped in globules on the floor where the wire passed into the cellar and the floor ignited, but the fire was easily extinguished. The house was provided with lightning-rods, one at each end of the building. The rod converged on the roof like the letter S, and from thence was carried down the back of the house into the earth to the depth of eight or ten feet. The rods were carefully insulated by means of glass, and all electric connection with the building cut off. The conductors were the grooved curved-iron rods in general use with copper points; the electric flash appears to have struck the rod on the west-end of the building (the point is fused and bent), and, being overcharged, a lateral discharge took place to the gutter which was lined or covered with tin. The fluid appears to have run along the gutter to the other end of the building as far as the tin extended, and then forced itself through the back walls into the house. I suppose had the rod been larger, or had the gutter been connected with the rod and the earth, the accident might have been averted. It appears to me that the rods in general are too small to carry off an extensive flash with that ease which is necessary to prevent a lateral discharge. What is your view of the matter?"

Naval and Military Telegraphy.—An exposition of the system of telegraphy for the joint use of the army and navy in combined military and naval operations, which has been brought to its present state of perfection by a series of experiments extending over some months by Captain Frank Bolton, of the 12th Regiment, and Commander Colomb, of her Majesty's navy, took place on Friday, the 19th inst., under the inspection of the Lords of the Admiralty, and was attended with the most perfect success. Their lordships had left Portsmouth in the afternoon in their yacht Enchantress, and anchored for the night in Cowes Roads, the Pigmy paddlewheel steamer, Master Commander Vine (fitted with sets of signalling apparatus), following from Portsmouth, and anchoring near the Admiralty yacht. The Pigmy thus became one point of communication, which may be termed the central, with the Lords of the Admiralty on board to watch and direct the proceedings. The Pigmy carries one of Captain Bolton's army field lime-lights, and is also fitted with the magneto-electric light of precisely the same nature as the one that throws its powerful rays nightly across the Channel from Dungeness Lighthouse. Commander Colomb was on board the Pigmy, and conducted the signalling, under the direction of the Duke of Somerset and his colleagues. The three outlying signal points from the Pigmy were —the semaphore tower, in Portsmouth Dockyard; Ash-down, in nearly the centre of the Isle of Wight; and St. Catherine's-hill, the high land near Black Gang Chine, at the southern extremity of the island. At the semaphore tower was one of Captain Bolton's army field lime-lights only, in charge of Captain Bolton and a corporal of Engineers. On Ash-down was a similar instrument in charge of a couple of Engineers or Sappers, and on St. Catherine's was a similar instrument, with also a magneto-electric apparatus, in charge of four Engineers. The time appointed for the signalling to commence was nine p.m., and the initiative was to be taken on board the Pigmy. It was considerably past that time, however, before the Pigmy made any sign to those in the semaphore tower at Portsmouth, and it was evident that the Lords of the Admiralty were either directing messages to St. Catherine's-hill in the first instance, or there must be an intervening fog between the signalling points undiscoverable from the semaphore at Portsmouth. The former eventually proved to be the case. Captain Bolton, anxious to discover the real cause, flashed his light in the direction of Ash-down, and the "call" being at once answered, Captain Bolton flashed the question as fast as the words could have been slowly spelt, "Have you any fog there, or is there any visible round St. Catherine's?" The answer, flashed as quickly back, was, "Nothing that we can see." The call signal from Portsmouth to Ash-down was made and answered, and these messages sent and received in two minutes thirty seconds. St. Catherine's station was next flashed into position out in the darkness, and told to keep a "sharp look-out." At ten p.m. the magneto-electric light on St. Catherine's-hill burst into view over Ryde, with all the brilliant intensity of a summer noon-day's blue sun, and "winked" out its message, "Cowes has seen us; good night." Portsmouth, however, was anxious to know what Cowes had said, and Captain Bolton, by a couple of flashes from his diminutive apparatus, checked his powerful friend and agent on St. Catherine's-hill, and put the necessary question. Again the wonderful light winked through the darkness, and, commencing its answer, said, "They asked us if we could." At this point Captain Bolton had to signal "Wait," for Commander Colomb on board the Pigmy at Cowes was calling attention with his magneto-electric light, and, on being answered, sent the following message (having no official meaning) to Vice-Admiral Sir Michael Seymour, at his residence in the dockyard, from the Lords of the Admiralty, who were on board the Pigmy, then from on board their yacht Enchantress:—"Semaphore tower, inquire of Sir Michael Seymour if the Channel fleet have coaled; ask also which boat won the race." This message was sent from the semaphore tower to the residence of Sir Michael Seymour, and an answer was sent across by the lime-light that—"The Channel fleet have not all coaled yet. Admiral Elliot's boat won the race." Their lordships now quitted the Pigmy for their own yacht, quite satisfied with the experiments, and a parting "Great success" again winked by the magneto-electric of the Pigmy to the lime-light on the Portsmouth semaphore tower closed the proceedings, and the Pigmy immediately weighed her anchor and returned to Portsmouth. It will be understood at once from the hour at which the signalling took place that only the night system of Captain Bolton and Commander Colomb was put under trial by the Lords of the Admiralty, and this course was taken for the reason that if difficulty in transmission existed in one part of the system over the other, it must be with the night rather than the day system, from the fact that fogs—that great enemy to all sight signals—are in greater force about the high lands of the Isle of Wight by night than by day. The magneto-electric light and the lime-light may be shortly described as follows:—In the magneto-electric the power that produces the light is resident in 120 permanent magnets, of about 50 lbs. each, ranged on the periphery of two large wheels, the latter driven by steam power, which causes 160 soft-iron cores surrounded by coils of wire to rotate past the magnets. The small streams of electricity thus generated are collected together into one stream, and by a special piece of apparatus, termed a commutator, the alternate positive and negative currents are all brought into one direction, and conveyed by a wire to the illuminating apparatus and "lamp," or "regulator." The lime-light is obtained from the ignition of a piece of lime, the shape and thickness of a small cedar pencil, by submitting it to the intense heat evolved by the compound flame of hydrogen and oxygen gases in the proportion in which they form water. The lime does not burn, but simply becomes brilliantly illuminated without undergoing any chemical change. This light is stated to be the most intense and pure known, with the exception of the electric light, over which, however, it possesses the great advantages of being steady and continuous, and its volume capable of being increased at pleasure. The cost of the magneto-electric apparatus is something like £2,000 at present, but it can be produced more cheaply as it is brought into use, and its cost of working is said to be comparatively trifling after it has been established. The cost of Captain Bolton's lime-light field

apparatus, complete for field service, and such as is now supplied by the War Department to our Royal Engineers, is about £35. The lime-light will receive and transmit signals with certainty to a distance of twenty-three miles. The range of the magneto-electric is greater. The lime-light is now supplied to every ship in the Channel fleet for night signalling, having superseded all other signal lights, and especially those with coloured glasses. The army and navy have thus already adopted the light officially to a certain extent, and it is with the object of its complete adoption throughout both services that Commander Colomb and Captain Bolton have now for some months past been employed upon these experiments to perfect a set of signals which may be introduced as the signal code for the conjoint use of the army and navy, and upon this part of their duties the commission to be named by the War Department and the Admiralty will immediately be formed and make a report. The entire system of transmitting the signals by day and by night is available under all circumstances, and is expressed by jets of steam, revolving shutters, a collapsing cone or disc by day; by one bright light by night, and by a fog-horn or steam-whistle in a fog. With these means the following results have been already obtained:—1. Perfect communication by day has been established between St. Catherine's Down, Isle of Wight, and her Majesty's steamer Pigmy, with the shutters and jets of steam, the Pigmy being 16 miles off at sea, at the rate of two signals in three minutes, including the transmission of the signals from St. Catherine's to the semaphore tower at Portsmouth, an additional 16 miles. 2. Perfect communication by night between the same points, at a seaward distance of 30 miles by the electric light, and a seaward distance of 22 miles with the lime-light, at the average rate of one signal per minute, the weather being ordinarily clear. 3. Fog signals by sound with common ships' fog-horns, at a distance of three to four miles, at the same rate of speed. Messages of 12 signals have been sent from St. Catherine's Down to the Pigmy, and *vice versâ*, at a distance of 17 miles seaward, in a gale of wind, and transmitted to Portsmouth in eight minutes, including the repetition at St. Catherine's. On the night of the 18th instant 200 signals were sent between Portsmouth and St. Catherine's Down in one hour. The new code may be said to be based upon the Morse telegraph, the short and long dashes in the printing of which are represented by Captain Bolton and Commander Colomb by the time the jets of steam, cone, or disc, or shutters, are exhibited by day; the time the light is flashed in by night, and the duration of the sound emitted by the steam-whistle or fog-horn in a fog. For exhibiting the light or cone on board ship, Commander Colomb makes the duration of the signal dependent upon a mechanical arrangement of his own invention, which leaves nothing to the judgment alone of the signalman, and makes use only of numerals, which are thus applicable to the present naval signal-books. In the telegraphic corps of the Royal Engineers, Captain Bolton's arrangements for fixed military stations, such as the semaphore tower at Portsmouth, as the head-quarters for telegraphic communication with all the surrounding fortifications are independent of any signal-book, the operator flashing each letter of a word from the point of his lime-light as he sends his message. It is evident, however, that this independent method would not answer at sea, where the flagship must keep repeating a message until answered by each ship in the squadron, and for this latter necessity Commander Colomb's mechanical regulator expressly provides, making and repeating the signal independent of any skill on the part of the seaman signalman.

MISCELLANEA.

The Reward of Genius.—While the exploits of the conqueror and the intrigues of the demagogue are faithfully preserved through a succession of ages, the persevering and unobtrusive efforts of genius, developing the best blessings of the Deity to man, are often consigned to oblivion.

The Preservation of Telegraph Poles.—The following composition is recommended to protect the bottoms of posts set in the earth:—Forty parts of chalk are added to fifty parts of resin, and four parts of linseed oil, melted together in an iron pot. One part of native oxide of copper is then added, and one part of sulphuric acid is cautiously stirred in. The mixture is applied hot with a strong brush, and forms, when dry, a mixture as hard as stone.—*Neues Jahrb. für Phann.*

Reporting by Machinery.—An instrument has been invented by Mons. Bryois for the purpose of taking short-hand notes with more than usual rapidity. It consists of a series of levers worked by keys like a pianoforte, and acting on types which impress themselves on a strip of paper that is gradually unrolled. It is said that an ordinary reporter, with one finger only, can work as quickly as the best short-hand writer, and that by using both hands the rapidity is immensely increased.

TELEGRAPHIC POESY.

O! lazy clerk, that sittest in the dark,
Awake and send a message, like a dove
With olive-branch, unto a little ark!
Go, take this merry message to my love.

O! lazy clerk awake the sleeping wires,
And let my thought flash swifter than the light;
Go, tell my love that when the sunset fires,
I shall be with her ushering the night.

—*Illustrated Times.*

Steadfastness.—He who remains in the mill, grinds; not he who goes and comes.

Relative Effect of Different Points upon Lightning Rods.—By means of an electric machine I charged a large metallic plate, representing a cloud, until a very sensitive electrometer marked 10°. I then gradually approached to the plate, first a rod rounded at its extremity, such as M. Despretz has proposed as the terminal of a lightning rod, afterwards an ordinary lightning rod point, and finally a very sharp point. These experiments gave me, as a mean, the following results:—1. The round-pointed rod remained without neutralising effect until it was struck, at a distance which I shall assume as the units. 2. The neutralising action of the common point did not begin until the distance was less than twelve units. 3. At the distance of twelve units, at which the common point had no neutralising action, the sharp point discharged the plate instantaneously. 4. The neutralising action of the sharp point began to show itself when the distance was less than 170 units. The neutralising action of the fine point, therefore, extended nearly 170 times further than the striking distance, or thirteen times further than the action of the common point.—*Comptes Rendus.*

TO CORRESPONDENTS.

K. R.—The list of telegraph companies promised in our last number is unavoidably postponed until next week.

L.R.—You must apply in the first instance to the lady-superintendent, who will examine you as to your qualification, &c.; the influence of a director would greatly assist you in the matter.

A Subscriber.—We believe that Mr. Haworth's invention is not in practical operation.

J. Mallet.—Apply to the secretary at the chief office, Gresham House. The company deserve well, as the initiators of cheap telegraphy.

A Reader.—Your communication respecting the telegraph clerks' fund will appear in our next number.

Anxious.—We have instituted strict enquiries, and find that there is no foundation for the report which appeared in several of the daily papers some two or three weeks ago, of the communication through the Persian Gulf cable having been interrupted; the only interruption being on the land lines, between Bussorah and Bagdad.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

Advertisements must be delivered to ensure insertion before Seven O'Clock on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	1 7 6
Half ditto	2 10 0	Four lines and under (single col.)	0 3 [illegible]

Single Advertisements from the country must be accompanied with stamps in payment.

THE EGHAM ACCIDENT.

HAVING satisfactorily shown, in a recent number, that this serious accident would indubitably have been avoided if the line had been worked upon the "block" principle, we think it would only be our duty to the Railway Company and our readers to give them our opinion upon the best system which they could adopt in carrying out this plan. The "block" system is the plan by which trains are maintained apart by a certain and invariable interval of space, instead of an uncertain and variable interval of time. Most railways have hitherto been worked on the time system. Experience and, notably, the Egham accident has proved this to be unsafe. Where fast express and slow goods trains are travelling over the same line, now through a thick fog, now up a wet incline, it is impossible to maintain that rigid interval of time which is essential to prevent collision. When, however, two trains, however rapidly or slowly they may be running, are invariably kept apart by an interval of two, three, or four miles, such accidents are impossible. This is effected by the "block" system. Railway companies are very chary of introducing this system, upon the plea that it produces delay, but practice shows that delays are not so excessive under its *régime* as under that of the old plan. Instead of keeping the danger signal on for five minutes, and the caution for five minutes more after the passage of each train, the signal can be lowered to "all right" immediately the train is signalled out of its length, and trains can run with perfect safety at intervals of two minutes, or even less. Every manager who has ever introduced the system upon his own line is found to advocate it strenuously, while its opponents are those who have never used it at all. It has had to run the same gauntlet as every other practical reform, and beat down all opposition by sheer force of truth and reasoning.

The chief object to be attained is that of making the next station practically a distant signal, to protect the line from any following train. This could be easily carried out, were it mechanically possible to work a signal two miles off, and blow a whistle that could be heard that distance; but as this is impossible, electricity has been made use of to supply the want. The moment a train enters a section of line its approach is announced to the station towards which it is going by the sounding of a bell or gong, and the line behind it is protected from any following train by a danger-signal being raised and maintained in that position until the train has passed clear of that section. This, it will be perceived, is just what is done by a distant signal within sight: the train approaches, the signal is put up, and it is not lowered until the train is clear. This is a very simple operation to perform, when the mechanical contrivances for effecting it are within sight and within reach. Great precautions are, however, required when that subtle force, electricity, is used. There are many ways employed to give this danger-signal; on some lines a small needle is deflected, and points to the words, "train on line;" on other lines the words are brought up to a small opening, and stare the signalman in the face. The South-Western Company makes use of the same signal to denote "danger" and "all right" in their telegraph instruments, as is used on the line itself. Thus where semaphores are employed on the line, a miniature semaphore is worked by electricity in the signalman's box; where discs are used, miniature discs are employed. A uniform system of signalling is thus adopted throughout the whole service.

To Mr. Cooke, the original introducer of the electric telegraph, must be accorded the merit of having first shown how a line might safely and economically be worked by the aid of the electric telegraph. He conceived a line of railway divided into sections, each of which should be governed by its own telegraph, and into which no second train should be allowed to enter until the first train had been signalled clear of it. Thus while a train was running from one station to another, the instruments at each station should show upon their faces that a train was running between them. The signal upon the instrument at the station from which the train started would be taken as a danger signal, until the train arrived at the second station, when it would be taken off and a second train allowed to proceed. The outdoor signals would follow the telegraph signals, and thus be practically worked by them. The telegraph signals thus become, to all intents and purposes, distant signals worked by electricity. The actual telegraph signal itself is not seen by the driver, but the signalman who has charge of the outdoor signals receives his instructions from the telegraph instrument, and the signals the driver sees are practically those of the telegraph. Thus distant signals can be fixed two or three miles away from a station, and in place of protecting a length of line varying from 500 yards to 600 yards from following trains, as is done at present by ordinary distant or auxiliary signals, that protection can be extended for miles, in fact to the next station. The question therefore arises, what is the best kind of system to use to convey clearly and unmistakeably, from one station to another, this *danger signal?* Many railway companies employ the ordinary instrument which is so extensively employed for ordinary telegraphic purposes. This is very simple and effective, but the use of the ordinary needle has many faults. The signals are liable to be reversed by lightning, and "line clear" may sometimes be given when "line blocked" is meant to be shown. The needles may be demagnetized altogether, and no signals whatever pass. The needle is sometimes loaded with cards having the words "train on line," or "line clear" printed upon them, adding immensely to the work to be performed, and increasing the liability to derangement. Perhaps the most perfect example of the needle system is that in use on the North Western line, and it answers admirably all the requirements demanded of it, but still it has all the defects of the needle system, and cannot be said to be that perfect apparatus which the necessities of such an important service require; the signals are under the control and can be actuated by the men at each station. This last defect is remedied in another system which is extensively employed, viz., that of Tyers. This instrument possesses many admirable points, but it has two or three serious defects in its construction and principles which diminish its value. It is worked by one line, and is actuated by momentary currents. The use of one wire may be advantageous in an economical point of view, but for actual efficiency it must be considered detrimental. Two opposite trains cannot be signalled at the same time upon a system based on such a principle, and if any accident arises the whole system is thrown out.

Systems based upon the use of momentary currents, and worked by one wire, are particularly liable to all sorts of accidental derangements. Atmospheric electricity may not only put the instrument *hors du combat*, but may actually produce a false signal. Deflections, those natural currents of the earth

that at times play such havoc with our speaking circuits, derange it completely. False signals may be given by many accidental and artificial causes. The wires might be brought into temporary contact by the wind, or, as they frequently were, by the long levers of the plate-layers, and cases have been known where birds alighting upon the wires have produced similar effects. The wrong button may be pressed, particularly in an instrument like Tyers', where the *same* signal has to be given at one time on one button, and at another time on a different button. The South-Eastern Railway Company have recently established a system based on this principle upon their Charing Cross extension, and we should not be surprised any day to hear of some calamity on that line arising from one of those accidental causes to which such systems are liable. It is so simple to give each line its own independent signal wire, worked by continuous currents, and free from those accidents to which the frail telegraph is peculiarly liable. The Metropolitan and the North Western systems do this, and so does the South Western, which is about to receive such extensive developments, owing to the lamentable experience of Egham.

The requirements of a railway signalling telegraph demand that there shall be a means of communication between two stations—not necessarily a speaking telegraph—which shall give notice of the approach, departure, and arrival of trains; that there shall be one signal to rule and protect the "down" line, and another signal to rule and protect the "up" line; that these three operations shall be conducted separately and distinctly, without interference with each other; that the man at one station shall have the complete control over the signal at the other, and that it shall be impossible for him to interfere or alter the signal at his own station; that every signal shall be acknowledged, and that the acknowledgment shall not only imply the due receipt of the signal sent, but that it has been properly understood and properly acted upon; and that any derangement of the apparatus, or the accidental delivery of a false signal, either by the man himself, or by the mechanical interruptions to which telegraphs are peculiarly liable, shall at once indicate danger, and produce safety. Any system that will undergo this crucial test with impunity, must be considered the *sine qua non* for railway authorities. We have carefully examined every system at present in work, both in this country and on the continent, and there are only two which will in any degree bear a comparison with the requirements we have laid down. They are the needle (Clark's, Spagnoletti, &c.,) and Preece's system, as employed on the London and South Western Railway; but the latter is immeasurably superior to the former, inasmuch as the man at one station has no control over the signals at his own station, and is firmly and fully assured by repeating signals that every signal sent is not only properly received, but duly acted upon. Indeed this system fully meets nearly every requirement we laid down, and is well worthy the deep study of every railway manager.

TELEGRAPHY BY INDUCED ELECTRICITY.

Voltaic batteries, those perpetual nuisances, are in a fair way to be reduced to a minimum. We have just had the pleasure of making some experiments with Mr. Thompson's induction machine. We described this machine some time ago, when it was being exhibited at the Whittington Club-house. It is a self-acting compound induction machine, excited and driven by four, five, or six Daniel's cells. This machine is the only one on the principle that has yet been made; and it was made as an experimental machine, and not for any special purpose. These machines are intended to be applied, not only to ordinary telegraphy, but also to telegraphy by electrolysis, and to the electro-depositing of metals; but, of course, each special purpose will require a special machine. This present machine, though only an experimental one, and not intended specially for any one of these purposes, nevertheless answers exceedingly well for all of them as far as we have yet seen it tested. We have seen it used on a needle instrument, a Morse, and electrolyticly; we have not yet seen it tried at electro-deposit; but we understand that extensive experiments are about to be made in that branch of electro-metallurgy. It has been erroneously supposed that an induction machine, of whatever construction, cannot possibly give electricity in any form but of the highest intensity and of quantity very small. Besides, since Mr. Whitehouse's experiments on the old Atlantic cable, electricians even have spoken of induction machines with a shudder, as though they must of necessity burn up all the coils of the instruments, and burst all the cables; but this machine clearly shows that this is but a gigantic Brocken shadow of the imagination that has frightened them.

We have tested this machine against the regular batteries used in telegraphy. We took a battery of sixty cells, the number used on the London, Chatham, and Dover Railway Telegraph line, to telegraph between London and Dover, and found on the Peltier electrometer that they had a mean tension of 12°, and on the galvanometer a quantity of 45°. The machine gave a mean tension on the Peltier of $8\frac{1}{2}$°, and on the galvanometer a quantity of 35°. Of course we need not tell electricians that the true ratios of tension are the square roots of 12 to $8\frac{1}{2}$—that is, $\sqrt{12} : \sqrt{8\frac{1}{2}} = 3{\cdot}46 : 2{\cdot}91$—which will make the tension of the machine equal to about fifty cells Daniel.

The quantity, of course, is in the simple ratio; that is, 45 : 35. Now, by calculation, taking the same ratios as for the tension, we get 45 : 35·9, which is nine-tenths of a degree more than our reading of the galvanometer gave us; showing plainly that the quantity and tension of this machine is governed by the same law as those of batteries. The machine was then put on the line, and spoke through to Dover very satisfactorily, though, of course, not quite so strongly as the sixty-cell battery, but more strongly than our testings would have led us to suspect. This line is eighty-two miles long, and there are twelve instruments in circuit upon it, each instrument having a resistance of six miles, that is, seventy-two miles; together the resistance is 154 miles,—a very adequate test for a machine of that tension.

To work a Morse by this machine, a reversary key and shunt are required to send a slight reversal through the instrument; but in a machine made expressly for working a Morse that would not be required.

In telegraphing electrolyticly the current from the machine decomposes nitrate of manganese quickly and strongly through 300 miles, and will do it very easily, but more faintly, through twice that distance; and all this is done with from four to six cells, and the inventor sees wherein he can modify the coils, that with half the number of cells he can get the same results.

THE OLD TELEGRAPHS.

Among the still primitive people of Montenegro a plan of transmitting information prevails which may be considered the rudest system of telegraphy still existing. When a shepherd in the mountains finds himself in want of society, he sends out at random a peculiar kind of yell, with a view of attracting the attention of any one similarly situated who may chance to be within hearing upon some other mountain side, and may also feel a desire for conversation. It is well known at what a great distance shrill sounds may be distinctly heard in these mountainous regions. The unseen friend, whose ears have caught the sound, responds in the same way, and then begins a dialogue about their flocks and herds, or any other country gossip; and should there chance to be news of public interest, such as of any important person or foreigner passing that way, the receiver of the intelligence shouts it out in the open air for the benefit of the mountain nearest to him, and so

it passes from one to another through a considerable part of the country. "This practice of calling from hill to hill," says a recent traveller, "also answers the purpose of an advertisement in a newspaper, and that with wonderful celerity. At any given time one-half of this badly-housed population may mostly be found in the open air, and their ears are astonishingly quick at catching these sounds. Any one who yells out his requirements may generally calculate on some one who has nothing else to do repeating them for him to the next living telegraph. An acquaintance told me he was once in want of a mule that was at the time grazing in the mountains more than ten miles off. He accordingly began the hue-and-cry: 'Ho! ho! you people there in the village of Brelizzu! High up in the mountains of Glenbotich, by the great beech tree with the withered boughs, the little lad Yanko is keeping my white-footed mule. Let him know that he is to come with it down to the road as fast as he can.' Thus the owner of the mule yelled at random into the air, and immediately some living echo took up his words, repeating them exactly; and so the message went till it reached the boy, and the owner of the mule found it waiting for him at the appointed place."

Beacon-fires were the ancient mode of telegraphy adopted in Great Britain, and in an act of the Scottish Parliament of 1455 it is directed that "one bale or fagot shall be warning of the approach of the English in any manner, two bales that they are *coming indeed*, and four bales blazing beside each other, that the enemy are in great force." The famous Bishop Wilkins, who pretended to discover the art of flying, describes certain alphabetic systems of transmitting information, which depended merely upon the number and alternate display or concealment of lights. The Marquis of Worcester, in 1663, described a system by which, as he said, a man at a window, as far as the eye could discover black and white, could hold discourse with his correspondent; and the ingenious Dr. Hook, in 1684, explained to a meeting of the Royal Society a scheme for communicating one's mind at distances of thirty, forty, a hundred, or a hundred and twenty miles, "in as short a time almost as a man can write what he would have sent." His plan required the use of the telescope, and was, of course, dependent on weather and various accidents; but this was the germ of the old semaphore which was actually used by our Government, and was at work in this country as late as 1852 between Liverpool and Holyhead. About twenty years after Hook's scheme was unfolded, an inventor, named Amontous, brought forward a similar plan in France. Persons were placed by him in several stations, at a certain distance from one another, and by the help of a telescope a man in one station was enabled to see a signal in the next before him. He was then required immediately to make the same signal, so that it might be seen by persons in the station after him. The signals used were either large letters of the alphabet or figures of various shapes to represent them. Amontous publicly demonstrated the practicability of his plan; but no system of signals was applied to any useful purpose till the period of the French Revolution. The telegraph then brought into use, in either 1793 or 1794, was the invention of M. Chappé, and, though similar in principle to the machine invented by Hook, it was greatly superior. The roof of the Louvre was his telegraphic terminus, and Chappé, having received from the Revolutionary Government a message to be forwarded to the army at Lille, he gave an understood signal to the heights of Montmartre, which was the second station, to prepare. At each station there was a watch-tower where telescopes were fixed, and the person on watch gave the signal of preparation throughout the line. The watcher at Montmartre then received, letter by letter, the sentence from the Louvre, which he repeated by his own machinery, and this was again repeated from the next height with as much rapidity as possible, until the message arrived at Lille. The upright post which was erected on the Louvre had at the top two transverse arms, movable in any direction by a single piece of mechanism. Chappé invented a number of positions for these arms, which stood as signs for the letters of the alphabet, and even these were reduced as much as possible. The signs, too, were arbitrary, so that they could be changed every week, all that was necessary being that the persons at each terminus should have the key. Two working models of this instrument were made at Frankfort, and sent by Mr. W. Playfair to the Duke of York, and thus the plan and the alphabet of the instrument came to England. Chappé was not more fortunate than other inventors in escaping opposition and discouragement. The people were prejudiced against the new machinery. His first instrument and station were destroyed by the populace; his second was burned to the ground, the unfortunate inventor narrowly escaping from the mob with his life; but the telegraph was subsequently taken up by the French Government, and became extensively used on the Continent.

This kind of telegraph, known as the aerial, was first established in England seventy years ago, a line of stations being formed from the Admiralty at Whitehall to the sea-coast, and information was thus conveyed from London to Dover in ten minutes. The expense of working and mounting the line from London to Portsmouth was £3,300 per annum. Though of great service to the Government, this old cumbrous system was, of course, only available in clear weather. Vexatious interruptions continually took place, and droll accidents occasionally resulted from the sudden cessation of communication, from a fog or similar cause, during the transmission of a message. When the British army were fighting under Wellington in Spain, news was anxiously expected from that great commander through the Admiralty signals. The public were in a state of feverish excitement, when one day the disastrous message was received: "Wellington defeated." The funds were violently agitated, the people and the Government were bewildered, and terrible rumours of enormous slaughter and great loss of guns, colours, and ammunition, were heard on all sides. It turned out, however, that just as the word "defeated" had been deciphered at some part of the line, a sudden mist had come on and cut off the remainder of the message. When this inopportune visitor had passed away, the public mind was instantly relieved with the news that the message was not "Wellington defeated," but "Wellington defeated *the French*."

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

V.

A.D. 1675.—Otto Guericke was contemporary with Boyle. He added the following discoveries to electric science:—An electrical machine with a globe of sulphur as the substance to be excited; the discovery of the light and sound accompanying strong electrical excitation; electrical repulsion; and that light bodies suspended within the sphere of action of an excited electric themselves become possessed of electrical excitation. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 43.)

A.D. 1676.—Mr. Haward, in 1676, relates of Grofton, master of the ship in which the circumstance occurred, that a violent thunderstorm reversed the polarity of the compass needles. (See *Philosophical Transactions*, July 18, 1676, pp. 647, 648; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 118.)

A.D. 1700.—Du Verney, in 1700, knew that the limbs of a frog are convulsed by the action of electricity. (See *Histoire de l'Académie Royale des Sciences*, 1700, p. 40; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 220.)

A.D. 1705.—Hawksbee used a glass electrical machine (1709), and made many experiments in respect to electric light. His discoveries extend from 1705 to 1711. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 43-45.)

A.D. 1707.—J. G. S., in 1707, published a German book, entitled, "Curious Speculations during Sleepless Nights." In this work occurs a notice of the electricity of the tourmaline as developed by heat. He affirms that the Dutch brought the tourmaline from Ceylon in 1703. (See Beckmann's *History of Inventions*, Vol. I., p. 89.)

A.D. 1708.—Dr. Wall, in the "Philosophical Transactions" for 1708, remarks, respecting the light and sound attendant upon the electrical excitation of a large stick of amber, as follows:—"This light and crackling seems in some degree to represent thunder and lightning. (See Bakewell's *Electric Science*, p. 12; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 44.)

A.D. 1720.—Grey and Wheeler's experiments extend from 1720 to 1736. The discoveries relating to tension electricity which these experiments embrace are as follows:—The ability to electrically excite metals when they are insulated (1729-31); that the human body is a conductor of electricity (1731); that when sulphur is fused and suffered to cool, it acquires a strong electrical property, particularly when it is cast in glass—certain resins have also a similar property; that the glass in which the sulphur is cast is also electrical; and that bodies may be preserved for months in an electrically excited state by wrapping them in worsted (1732). "Mr. Stephen Gray, just before he died, hit upon an experiment which seemed to indicate, that the attractive power which regulates the motions of the heavenly bodies is of the *electric* kind. The

experiment was this: he fixed a large, round, iron ball upon the middle of a large cake of rosin and wax; and exciting the virtue strongly in the cake, a fine feather, suspended by a thread, and held near the iron ball, was carried round it by the effluvia in a circular manner, and performed several revolutions: it moved the same way with the planets, from west to east, and its motion, like theirs, was not quite circular, but a little elliptical." (See *Encyclopædia Metropolitana*, Vol. IV., art Electricity, pp. 45-47; also *A new Universal History of Arts and Sciences*, Vol. I., art. Electricity, pp. 460, 461.)

A.D. 1729.—Gray and Wheeler, in February, 1729, produced motion in light bodies at a distance of 666 feet by means of frictional electricity. This experiment was tried with a view to ascertain the distance through which the electric force could be transmitted; it thus possesses an interest in connection with electric telegraphs. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 45, 46; also *Saturday Review*, August 21, 1858, p. 190.)

A.D. 1733.—Du Fay's experiments extend from 1733 to 1737. His discoveries are as follows:—That all insulated bodies may be electrically excited more or less; "that all electric bodies attract all that are not so, and repel them as soon as they become electric by the vicinity or contact of the electric body;" and that there are two distinct developments of electricity, one from excited glass, and the other from excited resin; bodies being electrified by the same substance repel one another, by opposite substances attract one another. Du Fay thus originated his dual theory of electricity. In some experiments Du Fay was assisted by the Abbé Nollet. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 46, 47.)

A.D. 1734.—Swedenborg, in 1734, in his "Principia," puts forward the following theoretical views in advance of the age in which he lived, and of interest to electricians:—1. Electrical effects are referred to a force less subtile than that producing magnetic effects. 2. Electrical effects are said to be produced by the gyration (movement in a spiral, helical, or circular path) excited by the tremulation of the particles of bodies. 3. Lightning is referred to the same origin as electricity. 4. Other polar forces besides magnetism are recognized, and amongst them electricity. 5. All forces moving in a spiral or helical path, and therefore magnetic and electric forces, vary in the inverse duplicate ratio of the distances. (See *Principia Rerum Naturalium, sive Novorum Tentaminum Phænomena Mundi, elementaris philosophice explicandi*. Fol. Dresden, 1734, in Vol. I. of "Swedenburgii Opera," pp. 410, 409, 427, 48, 49, 81, 60, 61.)

A.D. 1741.—Boze, in 1741, introduced the prime conductor, suspended from silk threads to the electrical machine, and "proved by many experiments that the weight of bodies was not affected by giving to them, or abstracting from them, electricity." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48.)

A.D. 1741.—Winkler, in 1741, in the electrical machine "substituted a cushion for a rubber instead of the hand." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48.)

A.D. 1742.—Dr. Desaguliers, in 1742, published an essay on electricity, in which he "distinctly divided bodies into "*electrics* and *non-electrics* or conductors;" he also accounted "for the superior success of electrical experiments in frosty weather, and in dry states of the atmosphere," by attributing it to the conducting properties of the vapour of water. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 47, 48.)

A.D. 1742.—Mr. Gordon, about 1742, used a glass cylinder for an electrical machine instead of a globe. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48.)

A.D. 1744.—Ludolf, of Berlin, about 1744, ignited combustible substances by the electric spark. He set fire "to the ethereal spirit of Frobenius." (See *Encyclopædia Britannica*, 8th edition, art. Electricity, p. 526; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48.)

A.D. 1745.—Dr. Miles, "observed the pencil of luminous rays proceeding from an excited electric, even without the approach of a conducting body." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48.)

A.D. 1745.—Dr. Watson, in 1745, made some experiments and researches respecting the electric spark, and "showed that in electrifying conductors of considerable extent, electricity is first developed at that part which is most remote from the excited electric." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48.)

A.D. 1745, 1746.—Muschenbroek and Kleist, in 1745, simultaneously discovered the Leyden jar. According to Dalibard, however, the inventor's name was Cuneus (1746). Exaggerated accounts were given of the effects of the shock from the Leyden jar by these philosophers; public attention was thereby drawn to the subject of electricity more by this than by any previous discovery. The Leyden jar was perfected by Sir W. Watson, Smeaton, Bevis, Wilson, and Canton. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 48; also Bakewell's *Electric Science*, pp. 14-17; also Sir W. Snow Harris' *Rudimentary Electricity*, pp. 58-74.)

A.D. 1746.—Dr. Watson, in 1746, proposed a single-fluid theory of electricity very like that of Dr. Franklin's. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 49.)

A.D. 1746.—Le Monnier, in 1746, showed that electricity was communicated to homogeneous bodies in proportion to their surfaces. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 49.)

A.D. 1746.—The Abbé Nollet, in 1746, found that electricity accelerates the efflux of fluids through capillary tubes. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 49.)

A.D. 1746.—Mr. Maimbray, at Edinburgh, in October, 1746, electrified two myrtle trees for a month, and found them put forth leaves and blossoms sooner than those that had not been electrified. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 49.)

A.D. 1747.—Pivati, in 1747, stated that the effect of medicines was conveyed through electrified glass tubes; it was afterwards found, however, that the electric force in this case performed the alleged cures. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 50.)

A.D. 1747.—Franklin's first communication to Mr. Peter Collinson, of the Royal Society, is dated March 28th, 1747. In these series of communications he propounds his single-fluid electrical theory. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 50.)

A.D. 1747.—Dr. Watson, in 1747, in the presence of many scientific persons, transmitted electricity through 2,800 feet of wire, and 8,000 feet of water, thus making use of the *earth circuit*. This fact is interesting in a telegraphic point of view. (See Highton's *Electric Telegraph*, p. 11.)

A.D. 1748.—Benjamin Franklin, in 1748, performed his celebrated experiments on the banks of the Schuylkill in North America. These experiments "were concluded by a pic-nic, when spirits were fired by an electric spark sent through the river, and a turkey was killed by the electric shock and roasted by the electric jack before a fire kindled by the electrified bottle." (See *Penny Cyclopædia*, Supplement 2; also *Saturday Review*, August 21, 1858, p. 190.)

A.D. 1748.—Jallabert, at Geneva, since 1748, "entertained the idea of submitting some invalids to electrical treatment, by drawing sparks from different parts of their body, which he brought near to the conductor of an electrical machine." Paralysis in the right arm was ameliorated by this means. (See De la Rive's *Treatise on Electricity*, Vol. III., p. 586.)

A.D. 1751.—Canton's discoveries range from 1751 to 1762. They are as follows:—That the excitement of positive or of negative electricity depends upon the rubber used, as well as upon the electric rubbed, and upon the condition of its surface; that a body of air in a state of rest can be electrified; and that an amalgam of tin can be applied advantageously to the cushion of an electrical machine. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 52.)

A.D. 1752.—M. Dalibard, in 1752, erected a lightning rod, and sparks from it were first observed by his assistant on May 10th. (See Bakewell's *Electric Science*, p. 21; also De la Rive's *Treatise on Electricity*, Vol. III., p. 92.)

A.D. 1752.—M. de Romas, in 1752, elevated an electrical kite, and obtained proofs of the existence of atmospheric electricity. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 134; also De la Rive's *Treatise on Electricity*, Vol. III., p. 92.)

A.D. 1752.—Franklin, in June, 1752, proved the identity of lightning and electricity at Philadelphia by his celebrated kite experiment. He immediately applied this discovery to useful purposes by inventing metallic conductors to protect buildings from the effects of lightning. (See Bakewell's *Electric Science*, p. 22; also De la Rive's *Treatise on Electricity*, Vol. III., pp. 91, 92; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 134, 135.)

A.D. 1753.—Professor Richmann, of St. Petersburg, in August, 1753, fell a victim to his experiments upon lightning, being killed by a thunder-clap whilst examining its effects upon an electrometer

of his own construction. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 52; also Bakewell's *Electric Science*, pp. 23, 24.)

A.D. 1753.—C. M., of Renfrew (Charles Marshall, of Paisley?) wrote a letter, dated February 1st, 1753, "to the author of the 'Scots' Magazine,'" proposing a plan for an electric telegraph. The insulated wires were supposed to be stretched in the air, and were to be equal in number to the letters of the alphabet; the signals were given by the rising of pieces of paper (bearing the letters) to electrified balls, or by the passage of a spark to certain bells, one bell answering to each letter of the alphabet. According to another method, the characters were kept constantly in contact with the balls by the continual passage of electricity through the line wire, except when a signal was to be conveyed, at which time the wire corresponding to the letter to be telegraphed was removed from the source of electricity at the transmitting station. Sir David Brewster shows that it is very probable that the "C. M." of Renfrew is identical with the "Charles Marshall," of Paisley—a person of whom an aged lady says, that he was a very clever man, who had formerly resided in Renfrew, and who could "make lightning speak and write upon a wall." (See *The Engineer*, December 24th, 1858; also a number of the *Commonwealth* (Glasgow newspaper); also *Chambers' Journal*, January 15th, 1859, pp. 47, 48.)

A.D. 1753.—Beccaria, in 1753, published the results of his experiments; they related to the speed of transmission of electricity through various media, and showed particularly the imperfect conducting power of water. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 52.)

A.D. 1759.—Mr. Delaval, between the years 1759 and 1764, communicated to the Royal Society certain experiments to ascertain "the conducting powers of the same body in different states." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 53.)

A.D. 1759.—Æpinus, in 1759, announced the production of electricity by heating the tourmaline, and that opposite electricities were developed in opposite points of the stone. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 53.)

A.D. 1759.—Mr. Robert Symmer, in 1759, in communication to the Royal Society, advanced the theory that there are two electric fluids, but that they are not independent of one another, as Du Fay supposed; on the contrary, they are co-existent, and simultaneously developed by electrical excitation. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 53, 54.)

A.D. 1759.—Æpinus and Wilcke, in 1759, electrified "two surfaces of a plate of air, so as to obtain a shock from the discharge of these surfaces, exactly on the principle of the Leyden jar." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 54.)

A.D. 1759.—Æpinus, in his "Tentamen Theoriæ Electricitatis et Magnetismi," published at St. Petersburgh in 1759, brought mathematical science to bear upon Franklin's single-fluid theory. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 54.)

A.D. 1760.—Canton, in 1760, discovered the electric excitability of the topaz upon the application of heat. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 132.)

A.D. 1762.—M. Sulzer, in his "Theory of Agreeable and Disagreeable Sensations," published at Berlin in 1762, noticed the peculiar sensation occasioned by a piece of silver and a piece of lead in contact with each other and with the tongue, and thought this effect might result from solution of either of the metals. This sensation is now known to be an effect of electrolytic action. (See Bakewell's *Electric Science*, p. 29.)

A.D. 1767.—Lane's discharging electrometer was contrived about the year 1767.—(See Sir W. Snow Harris' *Rudimentary Electricity*, p. 86.)

A.D. 1767.—Joseph Bozolus (a Jesuit, and lecturer on natural philosophy at Rome) invented "a practicable system of telegraphing, similar to that of C. M." (See a Latin poem entitled *Mariani Parthenii Electricorum*, in VI. Libros, Roma, 1767, p. 34; also *Saturday Review*, August 21, 1858, p. 190.)

A.D. 1771.—Mr. Henry Eales, in 1771, "originated a doctrine of opposite electric forces." (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 33.)

A.D. 1772.—Mr. W. Henley, F.R.S., in 1772, invented the quadrant electrometer. He also invented a "universal discharger." (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 78.)

A.D. 1774.—Lesarge, in 1774, "employed 24 wires and a pith-ball electrometer," to communicate signals by frictional electricity. (See Highton's *Electric Telegraph*, pp. 38 and 40.)

A.D. 1776.—Mr. Cavendish, in 1776, described an artificial torpedo, with which he exhibited the ordinary properties of this fish. (See *Philosophical Transactions*, 1776; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 54.)

A.D. 1776.—Volta, in 1776, made known the properties of the electrophorus. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 55.)

A.D. 1776.—Van Marum, about 1776, employed an electrical machine, consisting of a circular disc of shellac. (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 46.)

A.D. 1777.—Lichtenberg, about 1777, published his discovery of the phenomena of "electrical figures." These figures are produced by sifting pulverized sulphur and minium on to electrized resin. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 101.)

A.D. 1777.—Beccaria, about the year 1777, "found that a needle through which he had sent an electric shock, had, in consequence, acquired a curious species of polarity; for instead of turning as usual to the north and south, it assumed a position of right angles to this, its two ends pointing to the east and west. (See *Library of Useful Knowledge*, Electro-magnetism, p. 3.)

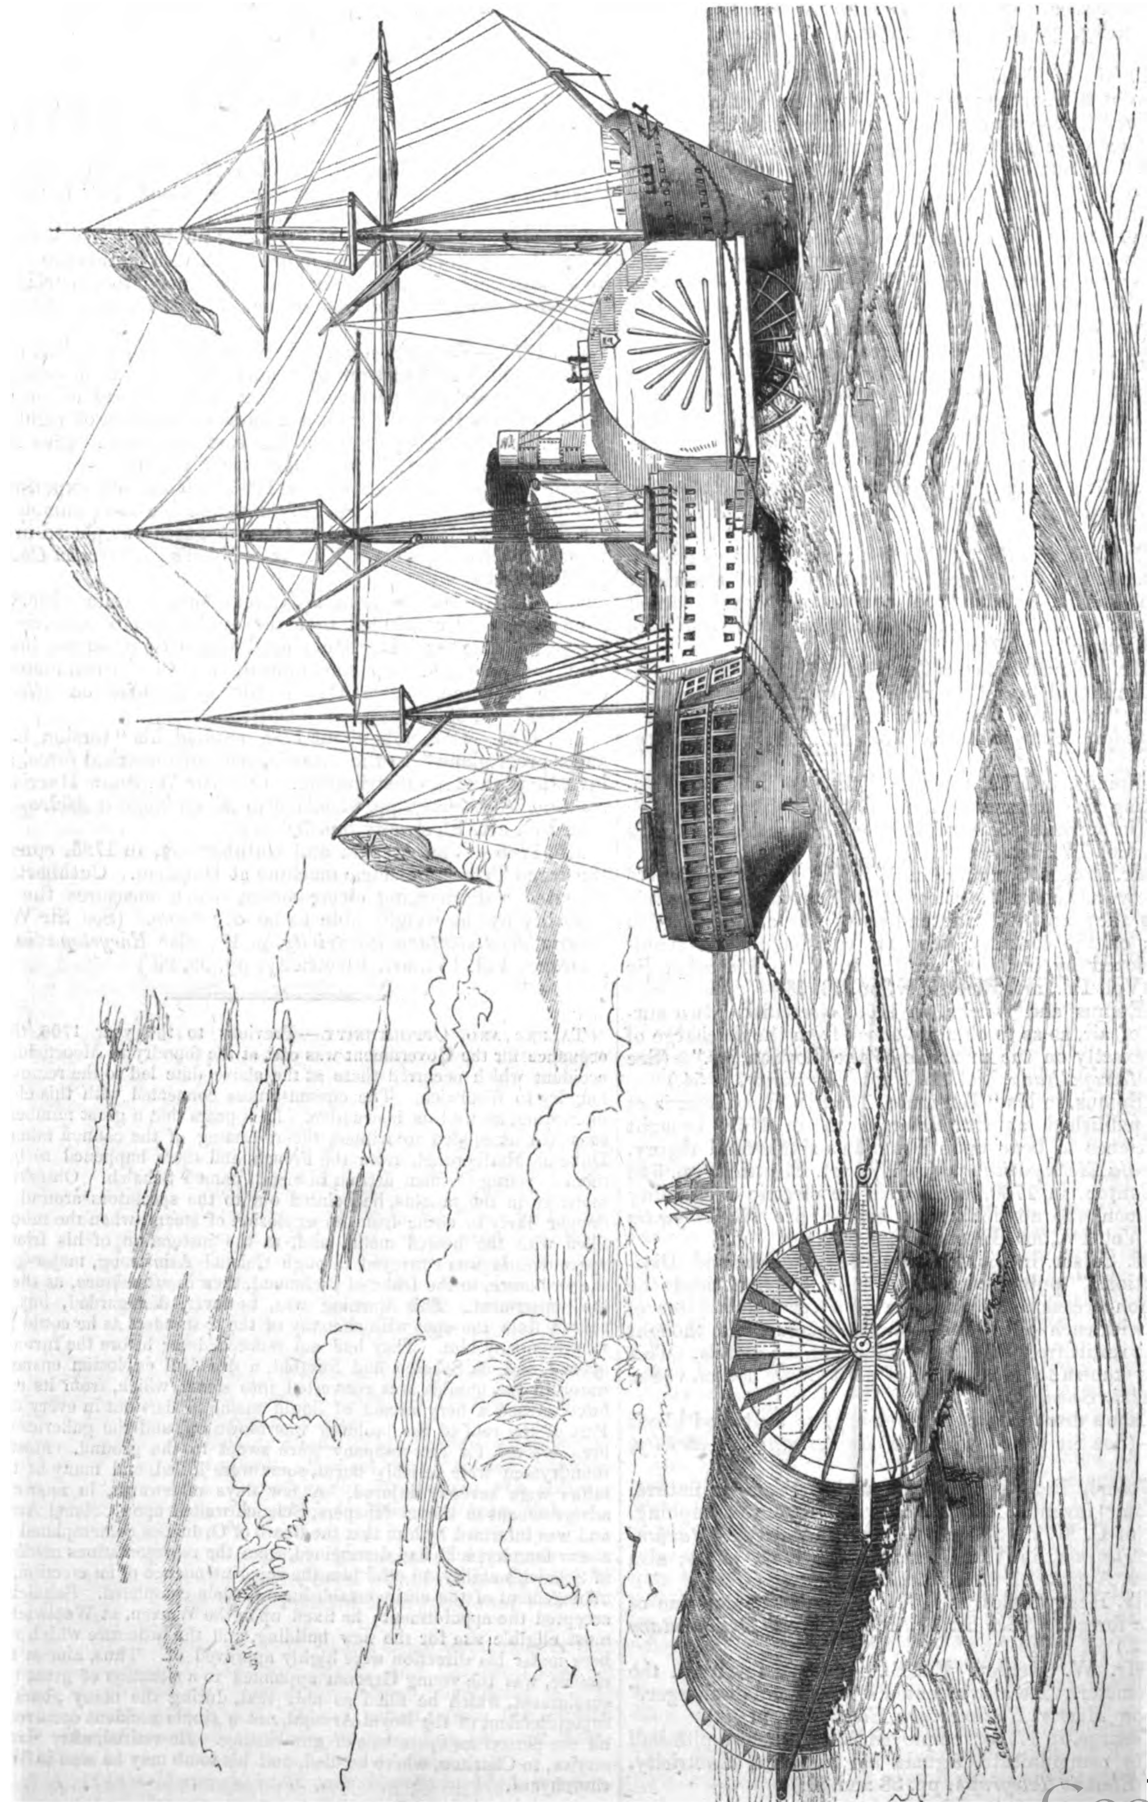
A.D. 1781.—Mr. Warltire, in 1781, related his experiment of producing water by the union of "inflammable and common air" to Dr. Priestley. The mixture of the two gases was placed in a close vessel, and fired by electricity. (See Noad's *Lectures on Chemistry*, pp. 182, 183.)

A.D. 1781.—Mauduyt, in 1781, published certain observations, from which he concluded that the application of electricity was favourable in paralysis. He placed the patient on an insulating stool, and put him into communication with the conductor of an electric machine. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 586, 587.)

A.D. 1785.—Coulomb, about 1785, applied his "torsion balance" and "proof plane" to the measurement of electrical force, and the investigation of its distribution. (See Sir W. Snow Harris' *Rudimentary Electricity*, pp. 81-83; also *Encyclæopdia Metropolitana*, Vol. IV., art. Electricity, pp. 70, 71.)

A.D. 1785.—Van Marum and Cuthbertson, in 1785, constructed the large Tylerian electric machine at Haarlem. Cuthbertson also invented a discharging electrometer, which measures the electric intensity by the weight able to be overcome. (See Sir W. Snow Harris '*Rudimentary Electricity*, p. 47; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 98, 99.)

TALENT AND OPPORTUNITY.—Previous to the year 1706 the brass ordnance for the Government was cast at the foundry in Moorfields, but an accident which occurred there at the above date led to the removal of the foundry to Woolwich. The circumstances connected with this change are interesting, as well as instructive. It appears that a great number of persons had assembled to witness the re-casting of the cannon taken by the Duke of Marlborough from the French, and there happened to be among them a young German artisan in metal, named Schalch. Observing some moisture in the moulds, he pointed out to the spectators around him the danger likely to ensue from an explosion of steam, when the moulds were filled with the heated metal, and, at the instigation of his friends, this apprehension was conveyed through Colonel Armstrong, major-general of the Ordnance, to the Duke of Richmond, then in attendance, as the head of the department. This warning was, however, disregarded, but Schalch retired from the spot with as many of the bystanders as he could persuade to accompany him. They had not proceeded far before the furnaces were opened, and, as Schalch had foretold, a dreadful explosion ensued. The water in the moulds was converted into steam, which, from its expansive force, caused a fiery stream of liquid metal to dart out in every direction. Part of the roof of the building was blown off, and the galleries that had been erected for the company were swept to the ground. Most of the foundrymen were terribly burnt, some were killed, and many of the spectators were severely injured. A few days afterwards, in answer to an advertisement in the newspapers, Schalch waited upon Colonel Armstrong, and was informed by him that the Board of Ordnance contemplated building a new foundry, and had determined, from the representations made to them of Schalch's ability, to offer him the superintendence of its erection, and the management of the entire establishment, when completed. Schalch readily accepted the appointment; he fixed upon the Warren, at Woolwich, as the most eligible site for the new building, and the ordnance which were cast here under his direction were highly approved of. Thus, almost by mere chance, was the young German appointed to a situation of great trust and emolument, which he filled so ably that, during the many years he was superintendent of the Royal Arsenal, not a single accident occurred amidst all the dangerous operations of gun-casting. He retired, after sixty years' service, to Charlton, where he died, and his tomb may be seen in Woolwich churchyard.



CAPTAIN SELWYN'S (R.N.) APPARATUS FOR PAYING OUT ELECTRIC TELEGRAPH CABLES.

FLOATING CYLINDERS.

By J. H. Selwyn, Captain R.N.

Some of our correspondents having expressed a wish that a full description of the proposed arrangement for laying submarine cables by Captain Jasper Selwyn, R.N., should appear in this journal, it affords us much pleasure in thus being able to comply with the request. We believe that it is intended to construct a cylinder of considerable dimensions with the view of practically testing its applicability and efficiency for the purpose :—

One, two, or more cylinders, if preferred, of plate iron, ½-inch thick, are constructed to carry such portion or portions of the cable to be laid as may be thought desirable; but as it is most convenient to make the necessary calculations on some known basis, the old Atlantic cable will be first taken as an illustration.

That cable weighs one ton per mile in air; in water, 14 cwt.

Its diameter is ⅝ths of an inch.

Its cost about £100 per mile.

The distance laid is 2,022 miles, and the distance between Valentia, Ireland, and Trinity Bay, Newfoundland, is 1,650 nautical miles; 3,000 miles will be taken as necessary in these calculations.

The size of cylinder, with paddle wheels attached, which will carry 1,500 tons, or half the cable, at less than half immersion, say about 20 feet draught, is 60 feet long and 50 feet diameter, this gives a tonnage of 3,366.

Of ½-inch iron plate throughout with double ends, 3 partitions, wheels, frame and stays, rivets, angle iron, &c., the rough estimate of weight is 300 tons, which at £20 per ton (to allow for manufacturer's profit) will be £6,000 total cost.

But the present light cables may be carried at considerably less expense, if, indeed, one or two thousand pounds be considered an object in carrying a cable, whose cost must be reckoned by hundreds of thousands, and in which a difference of 6d. per lb. in the expense of manufacturing the gutta-percha would more than cover the whole of the cost of laying by these means, that difference (as 400 lbs. of gutta-percha are used in each mile of 3,000 miles) being equal to £30,000.

The draught of water of such a cylinder will be about 6 feet when light, and it would in that state take a weight of 5 tons at 10 feet from the centre to deflect it one quarter of a degree from the horizontal. It may be proved by hydrostatic pressure, as is done with steam boilers, and it may be made to pump itself out whenever revolving.* Its resistance to towing will be considerable when not laying cable, but not sufficiently so to be really objectionable, as one steamer it is well known can tow another of her own size at a very small diminution of her speed. Many instances could be given of this fact, which is only a proof of the correctness of the theoretical axiom that the velocity of a ship varies as the cube root of the power, and *vice versâ*.

To put it in plainer language, if 800 horse-power propel a ship 10 knots, then two ships of equal size will be propelled by the same power acting in one of them, not 5 knots, but 8 nearly.

Note.—Captain Ericson's small screw vessel, of 45 feet length, 8 feet beam, and drawing 2 feet 3 inches of water, towed the American ship Toronto, of 630 tons burthen, on the Thames, 25th May, 1837, at the rate of 4½ knots per hour against tide.

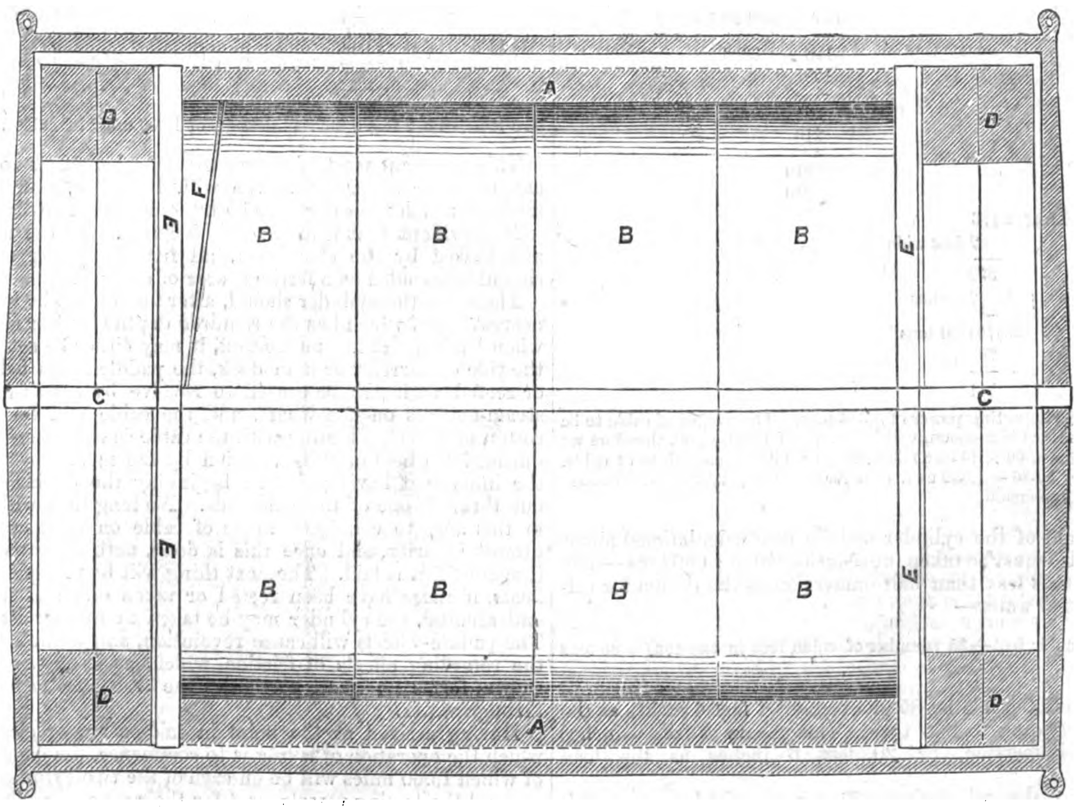
But the resistance is lessened during the laying of the cable by the fact, that with every mile thrown off the cylinder rises out of the water, and not only gives a less immersed midship section, but a better formed one, a smaller segment of a large circle.

The towing is also rendered less difficult than that of a ship by the fact that a cylinder so towed does not sheer about, or pitch and roll, these being the great causes of jerks and strains, which often break the towing cables.

If a gale of wind come on during the laying, not only is all anxiety about the ship and crew done away with, but even if separated from the towing vessel altogether no breakage of the cable could take place, for the cylinder is always free to revolve in answer to a steady strain, and there being no pitching or rolling, no other strains need be apprehended.

* Paddles are attached to each end, and it has a frame by which it is towed; the paddles cause and regulate its revolution.

FRAME BY WHICH CYLINDER IS TOWED.



Plan—Scale 1-16 in. to 1 foot.

A, Cable. B, Cylinder in four compartments. C, Axle hollow. D, Paddles. E, Double Ends. F, Tube through which inner end of Cable is led.

If during the laying the cable should by any accident be broken, means are provided (sufficiently simple in their character to give a fair chance of success) by which the cable may be caught and held, even miles astern of the ship, until she can go back, and picking it up, make a splice, and proceed anew. If the cylinder be cast off, or the tow ropes broken, so soon as any strain is felt upon the cable by the drift to leeward of the cylinder, the result will be that the cylinder will turn round and "ride to" the cable, veering slowly in answer to the strain, but resisting any rapid pulling off of cable by the beating of the paddles on the water. But with proper management this breaking adrift ought not to occur.

Arrangements are made for reefing or expanding the paddles during revolution, so as to regulate the amount of slack or tightness of cable as desired. Also for testing through the cable electrically during the coiling on or laying, by passing the end of the cable, which is first coiled on, out through one of the axles; there it is allowed to turn freely, in contact with a spring, or dipping into a cup of mercury, as preferred. To give a familiar idea of the size of the cylinder, it may be stated that it is about as long as an ordinary coal-barge on the Thames, or a little less than the distance between any two neighbouring lamp-posts along the street. It has been stated that the size of cylinder for such a cable as the late Atlantic would be 60 long × 50 diameter, that its weight was about 300 tons, and the total cost about £6,000. We will now proceed to give the details of these calculations of weight and cost of cylinder for carrying a submarine telegraphic cable, such as the old Atlantic:—

	Ton	cwt.	qr.
Weight in air per mile	1	0	0
Weight in water per mile	0	14	0
Diameter	⅝-inch.		
Length	3,000 miles.		

This can be carried thus. Two cylinders are to be built of ½-inch iron, each 60 feet long by 50 feet diameter, with double ends 2 feet apart, and paddle-wheels attached, the ends to have a diameter of 56 feet, and the whole to be surrounded by a frame, in which the axles revolve. The tonnage of each of these will be as follows:—

```
                 Area of 50 feet = 196350
                                   60 length
Cubic feet in one ton 35)11781000(3366 tons burthen
                         105        add 20 for ends
                         128        3386
                         105
                          231
                          210
                           210
                           210
Ends area of 56 feet = 176
                     2 feet wide
                     352
                     2 inches
                 35)704(20 tons
                    70
                     4
```

Thus we get a total supporting power of 3,386 tons. The weight of cable to be carried at, say, one-third immersion, will be thus, ⅓ of 1,500 = 500, therefore we have 1,000 tons plus (500 × 14 cwt.) 350 tons, or 1,350 tons weight of cable. The gross tonnage 3,386 — 1,350 cwt. of cable = 2,036; 2,036 — 1,350 = 685 tons less than half immersion.

Now the weight of the cylinder will be (see calculations) about 300 tons; this also must be taken into consideration; 686 tons — 300 tons leaves 386 tons less than half-immersion as the datum for calculating draught of water—

60 × 50 = 3000 cubic feet ÷ 35 (number of cubic feet in one ton) = 85 tons for the first foot.

Now, roughly dividing 386 by 85 gives about 4 feet 6 inches as the draught corresponding to 386 tons. This means 4 feet 6 inches less than half-immersion, or 20 feet 6 inches as the load draught.

Next we take the calculations of weight, which are as follows:—

Barrel.

Length of Cylinder.		Circumference of 50 ft. diameter.				1¼-inch. No. of lbs. in 1 sq. ft.		Weight of Barrel.
60 feet	×	157,080	=	94,248	×	20	=	188,496 lbs.

3 Partitions.

	Area.		In No.					Weight of Partitions.
50 feet	= 196,350	×	3	= 589,050	×	20	=	117,810 lbs.

4 Ends, 56 Feet Diameter.

	Area.		In No.					Weight of Ends.
56 feet	= 246,301	×	4	= 985,204	×	20	=	197,040 lbs.

Assumed weight of frame, wheels, stays, rivets, angle iron, cuttings, &c., 80 tons, or = 179,200

```
2240)682,546(304½ tons
     672
      1054
       896
       158
       224
```

Total weight of cylinders and attachments 304 tons, multiplied by £20 per ton to get probable total cost, gives £6,080.

Next there is the calculation of the thickness of cable when reeled on cylinder, the total number of miles in one layer, and the number of layers on the cylinder when 1,500 miles are coiled on:—

Diameter of cable, ⅝ths of an inch; length, 1,500 miles; mean diameter of cylinder and cable, 52 feet; length of barrel, 60 feet.
Then

```
Circumference of 52 feet                         = 163·36
Number of turns of ⅝ths of an inch in 60 feet      1153·4
                                  1153·4
                                  163·36
                                  69204
                                 34602
                                34602
                               69204
                              11534
No. of feet in one nautical mile 6082)188409·424(30·9
                                      18246
                                        59594
                                        54728
Miles of Cable.
30·9)1500·0(48·5 layers
     1236
      2640
      2472
       1680
       3090
```

48·5 × 5 ÷ 8 = 2 feet 6 inches thickness of 1,500 miles of cable when reeled on.

This sums up most of the necessary calculations so far as they can be made at present. We will, therefore, now consider the mode in which the cable is to be treated on these cylinders.

It is evident that when a cable is finished by the manufacturer, and passed by the electrician, all further coiling and uncoiling should be avoided as a fertile source of damage.

Therefore the cylinder should, after launching, be brought to the nearest wharf which has the required depth of water for its flotation when loaded. Being moored off, it may either be set in motion by the tide or current, or if in dock, the paddle floats being taken off or reefed in, it may be caused to revolve by bands from portable steam-engines on the wharf, and the cable will be coiled on as cotton on a reel. Testing with the cable *in water* can be carried on during the whole of this operation by the means before spoken of, the inner end having (before beginning the coiling) been passed out through one of the axle-ends. No long time will be required in this way to coil 1,500 miles of cable on each cylinder in the utmost security, and once this is done, nothing but water touches it again till it is laid. The next thing will be to replace the paddle floats, if these have been reefed or taken off; and now, with the end secured, the cylinder may be taken in tow for its destination. The paddle-wheels will cause revolution, and diminish by so much the retarding effects of friction, which, as Professor Rankine has shown, forms no small portion of the resistance to bodies passing through water.

Having arrived at the point in mid-ocean, or elsewhere, from which the operation of laying is to commence, the ends of the cable, of which 1,500 miles will be on each of the two cylinders, are joined up, and the towing vessels start for their respective shores.

It would at first sight appear that great difficulty will be expe-

rienced in towing so large a body, broadside on, as it were; but so far from this being the case, serious fears were entertained by one of our best mathematicians lest the cylinder in deep water, with a very heavy cable, should go at such a speed by itself as to "run over the ship." It is scarcely, however, necessary to consider this possibility—admitting that it does exist—because no very heavy cable need be laid in such a depth. One ton per mile will be quite as much as will ever be tried for crossing the Atlantic, and it is probable that even this is very unnecessarily heavy.

Let us, however, examine why it *is* possible, under certain circumstances, for the cylinder to run over the ship.

The descending cable weighing, be it recollected, even in water, 14 cwt. per mile, operates on the cylinder exactly as does the weight on the barrel of a clock movement.

It sets the barrel or cylinder in revolution, and this revolution is always tending to increase in velocity until the depth of water, and consequently the weight suspended, diminishes.

But this revolution cannot take place without causing the paddles to strike the water, and thereby propel the cylinder.

Given a depth of water two miles, weight of cable 14 cwt. in water per mile, then 28 cwt. are constantly applied to the rim of a wheel whose diameter is 50 feet, tending to turn it round in the water, which tendency being resisted by the paddle floats, causes forward movement of the whole body.

But it must be remembered that this will only take place so long as the cable is perpendicular in its descent. When this is altered by the forward movement of the ship towing, and the angle of 45° is passed, the backward pull becomes equal to the forward impulse, and no other effect is produced than a resistance by the paddles to the pull due to the weight of cable.

The result of all this is, that if the ship be able to go fast, the weight of cable does not assist her; if, on the contrary, she be reduced to the two-miles-an-hour speed, which is about the rate at which the cable can sink, then the whole effort from this cause will come in aid of the engines towing.

To return to the operation of laying. Any speed judged desirable, or which the towing vessel is able to accomplish, may be kept up regularly and without danger. A speed of 10 knots would cause the cylinder to revolve at the rate of about six turns per minute, or the outside of the cylinder would have speed of 1013·6 feet in a minute, which for a paddle-wheel is not excessive, the Great Eastern having considerably more. Supposing each ship to have gradually reached even this speed, and that the curve of cable between them were 100 miles, it is clear that any surge caused by a wave would be felt—first by the ship; next by the cylinder tow ropes, which will always have an elasticity due to the catenary curve in which they must hang, and then by the cylinder; last of all, and but slightly, by the cable, which is at no time absolutely checked in its unwinding.

When the pull comes on the cylinder the immediate result is to bring a greater turning force on the paddle floats, and thereby to give off more cable than the 10-knot speed required.

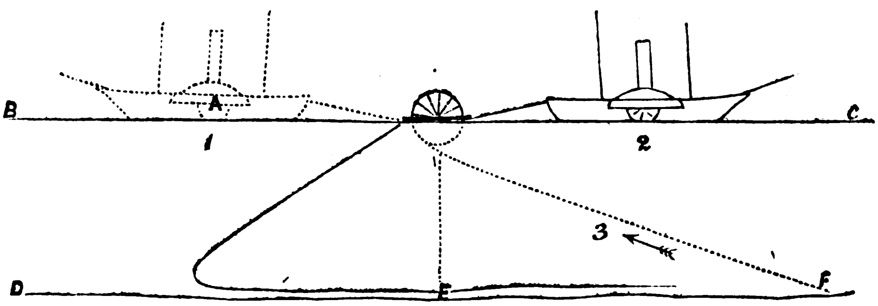
Further, to obviate any possible strain to the cable, there is a provision, as has before been stated, for expanding or reefing the paddle floats while towing, so that at will the diameter of the wheels which govern the revolutions can be increased or diminished relatively to the barrel of the cylinder, the result being that as much, or as little, slack is laid as may be proper.

But it is never a matter of necessity to continue the operation of laying, if the weather be such as to render it hazardous to do so. The ship need only "lie to," and either veer out a long scope of tow rope, or detach altogether, putting such brake power on the wheels of the cylinder as shall secure its not turning under a certain strain, to be less than half the breaking strain, and then waiting for more favourable weather.

If a leak should be feared in a structure which can be proved like a steam boiler, it is easy, by means of radial scoops internally, to make the cylinder pump itself out (as is done in the modern process of refining sugar) whenever it is revolving.

While there is great depth of water, and consequently great suspended weight of cable, the wheels will be deeply immersed, and great resistance will be opposed to any more cable being dragged off than the percentage of slack which has been decided on. If the depth alters, the resistance immediately increases or diminishes with it, by the weight of cable hanging under being also altered, and as the cable goes off the cylinder rises out of the water, opposes less resistance to towing, and has fewer floats immersed. As the shore is approached the draught of water will have lessened, so that the cylinder itself may, if requisite, be towed into the harbour, instead of a second shifting into boats, which may easily be a cause of damage.

The cylinder may also be easily used in either underrunning or picking up the cable for repairs. If, for instance, the cable were broken between the ships at the outset of the operation of laying, and by any mischance the means provided for catching the end did not take effect, then each ship would cast off her tow ropes, where they are hooked or joined to the foreside of the towing frame, and again make fast to the after or hinder part of the said frame. As soon as the ship again begins to tow, the cable will be wound *on* the cylinder, if sufficient velocity be attained to overcome the weight of cable due to the depth, by the resistance of the paddles; and this may be done, if necessary, in circles, taking care to follow the lay of the cable. It has been found, in performing this operation with the model, that the cable is picked up as shown in the diagram.



1. Ship laying. 2. Ship picking up. 3. Former line of laying.

What is meant, therefore, is, that if we think that the line from E to D is getting too long, instead of continuing towards C, we may tow round and round in circles, so as to pick up the cable without going on over that already laid, until the slack or loop from cylinder to D E is reeled on. In thus reeling up, either manual or mechanical means must be provided to guide the cable, so that the turns may not "ride" or overlay each other. But there is little reason to anticipate any necessity for this operation in deep water, where it is admitted that it would be attended with considerable difficulty, though even there not impracticable with a good cable, if the cable be only properly laid without kinks and without strain, as may be one by these means.

It will, perhaps, not be out of place to advert here to the nature of cable which should be used, and without going too much into particulars, shortly to state what are the absolute requisites for success.

It is evident that to the safety of the conductor and its insulator, after manufacture and testing, all other considerations must be subordinate; therefore, when the size and shape of these have been determined, any application by which there is even a remote chance of injuring them must not for an instant be allowed. Among the most prominent of these applications is the system of outer wires, which has, in all cables hitherto laid in deep water, contributed far more to their destruction than their protection, whether by causing heating in the hold of the vessel in which they were stowed, or weakness by their weight and liability to destruction at the bottom; whether viewed as the protecting arch, which they are not, or the mechanical fallacy, which they are, naked or with a skin of gutta-percha, spiral or in straight lines, they are an error, and must be abandoned.

Where, then, shall we look for strength? how shall we provide for raising *the cable we wish to lay?* Is it necessary to do so? Are

there any probabilities, not to say possibilities, of raising a great length of deep-water cable? Should we not rather provide for its safe deposition than for first breaking it, and then raising for repairs? Is it not the fact that all who think much on the subject agree in believing that a simple insulated copper wire would be the best after all, if it could be submerged without being subjected to strains? But if strength we must have (we are, of course, not now speaking of shore ends), then it is clear that it must be protected strength—strength as little liable to decay as possible, and the greatest in the least bulk. These conditions point unmistakeably to steel as the material, and contact with the conductor as the place for it. Then both conductor and strength are alike protected from the fatal admission of salt water. Then they will be inseparable during life, and in their deaths (if that unfortunately occur) not divided; then wire rope will not blame gutta-percha, nor will gutta-percha suffer from the too strict embraces of its hitherto faithless ally. We shall get no more shrugs of the shoulder over submarine telegraphy and its moral causes, our shares will be at a premium, and our shareholders will buy as well as sell.

A company is being formed in the full persuasion that they *can* see how to do it, as well as how not to do it, and it is confidently hoped that before many months elapse submarine telegraphy will again raise its voice, and look both friends and foes fairly in the face.

CORRESPONDENCE.

INDIA-RUBBER CABLES.

To the Editor of the Telegraphic Journal.

Sir,—Your correspondent "Beppo" has miserably failed in his attempt to controvert the damaging facts adduced by Mr. Henley and myself. He has not furnished a single instance in which india-rubber insulated wires have lasted for any length of time. The material has had ample opportunities and fair play to prove its efficiency, but under both experimental and practical tests it has proved itself inapplicable for the purpose of telegraphy. I ask again—"Can 'Beppo' prove the contrary?"—Your obedient servant,

R. Watson.

TELEGRAPHIC NEWS.

The Persian Gulf Cable.—From a telegram received from Bombay, viâ the Malta and Alexandria line, we are sorry to learn that the above cable has been broken; the particulars of the accident have not, however, yet been received at the India Office.

Tampering with Telegraphic Wires.—Placards were extensively issued, on Monday morning last, offering a reward of £50, on the part of the directors of the South-Eastern Railway Company, for the discovery of the person or persons who recently rendered the telegraphic communication on the North Kent line inefficient by means of connecting together, with a piece of copper wire, the wires relating to telegraphic instruments at the Woolwich Arsenal.

The Transatlantic Telegraph.—The telegraph across British North America, according to the *Montreal Gazette*, is progressing favourably. Dr. Rae, the Arctic explorer, employed by the Hudson's Bay Company to visit the country between between Red River and the Pacific coast, to select the proper line for the telegraph, reached Fort Garry about two months ago, and is now far on his way across the plains of the Saskatchewan. Seventy-seven tons of the wire, nearly half the quantity required, have arrived in Montreal. The wire is to be forwarded at once by the Grand Trunk Railway Company to Sarnia, and by steamboat to the head of Lake Superior, whence it will be transported during the winter to Fort Garry on the Red River, at which place the whole of the wire, instruments, insulators, &c., will be collected by the beginning of spring. The poles will be cut and got ready during the winter. As soon as the weather of next spring sets in active operations will be commenced, and by the close of the year 1865 there is every reason to expect that the telegraphic communication will be in operation from Fort Garry to the shores of the Pacific. The telegraphic system of the United States is in operation to within about 400 miles of Fort Garry. "This gap," says the same paper, "will certainly be at once filled, and the messages can pass from any part of Canada to British Columbia. Will not Canada be prepared to complete the communication between Fort Garry and Montreal by the Ottawa Valley, so as to have an unbroken line of telegraph stretching from the Atlantic to the Pacific through British territory? This active prosecution of the Pacific telegraph by the Hudson's Bay Company is the best evidence of their intention to inaugurate a new policy in their affairs. The progress of the telegraph with the company's posts every forty or fifty miles will be the surest means of opening up the country, and directing to the fertile territories of the Saskatchewan, the Assiniboine, and the Red River, a tide of settlement and population which will ultimately complete the chain of British colonies from one ocean to the other."

India Telegraph.—Col. Stewart, C.B., whose successful completion of the Persian Gulf telegraph we have already reported, arrived on Monday from Bombay, viâ Egypt. Lieut-Col. Goldsmith, who started almost simultaneously from Bagdad, on a mission of inspection of the land line thence to Constantinople, is also expected in the course of the week, having reached Angora on Monday. On the arrival of the latter officer, definitive arrangements will be made by Col. Stewart and him, in concert with Mr. Courtenay, the delegate of the Indian Government, for the regular working of the through Anglo-Indian service as soon as the line between Bagdad and Bussorah has been completed.

The American Army Telegraph.—The correspondent of the *New York Times* gives the following account of the army telegraph:—"The wires of the army telegraph are insulated, and may be unrolled, with great rapidity, from a winch in a waggon constructed for the purpose. As the waggon moves forward the wire is left to trail on the ground, or is placed upon light portable poles with pointed ends for thrusting into the soil, or is simply rested upon branches of trees by the roadside, as it threads its way through all the corps' head-quarters, and converges from every direction to the position of the general commanding. When the army moves the wire is taken up by the winch just as quickly as it was laid, and is ready for use at the next stopping place."

Telegraphic Communication between India, Singapore, China, Java, and Australia.—The project which has been for some years on foot for establishing a complete system of telegraphic communication between India, Singapore, China, Java, and Australia, is about to take the first step towards realisation. The Anglo-Australian and China Telegraph Company (Limited) have issued their prospectus for private circulation, and we understand that it will shortly be published. The present proposition is to to raise £450,000 for laying down a submarine cable between Rangoon and Singapore. This line will place India in direct telegraphic communication with Singapore and the Straits of Malacca, thus also reducing the time of communicating with Java, the Straits of Sunda, and China, to little more than the time occupied by the mail steamers between Singapore, Batavia, Hong Kong, and Shangai. The India and Singapore line will also enable news to be telegraphed to Galle and Bombay, in connection with the mail steamers which leave those ports five times a month. The shipping interests will be especially benefited by the India and Singapore line. Nearly the whole of the telegraphs proposed by the company can be laid in a moderate depth, say about fifty fathoms, the only portion of the seas proposed to be traversed that is not sounded being that which lies between the east end of Java and the Island of Timor. Everywhere else the moderate depth indicated is known to prevail, and that portion not sounded is only about 800 miles. Intermediate stations will be established every 400 to 500 miles, and the proposed submarine telegraph will be divided into sections of convenient lengths. Should the land line through Turkey or Persia prove efficient, the India and Singapore telegraph will place Europe in direct telegraphic communication with Singapore, but without relying upon those lines the efficient working of which has yet to be proved, the value of the proposed line will be very great, and will accommodate the important trade between India, Singapore, and China, and of the Straits Settlements, besides affording a communication with Galle and Bombay in connection with Europe. The Dutch government have granted a provisional subsidy for the extension of the proposed line from Singapore to Batavia, and the Australian colonies will no doubt recover the large subsidies voted or promised in 1860, when Mr. F. Gisborne proceeded to Australia to obtain financial assistance for a line from Java to Australia. The only existing line which affords any parallel to those proposed by the company is that which was laid three years ago by her Majesty's Government between Malta and Alexandria. The working of that line has been highly satisfactory. It has, indeed, been twice interrupted, but owing to the circumstance that it was laid in a moderate depth along the African coast, it was easily repaired on each occasion, the delay in effecting the repairs being due to the circumstance that there was no steamer available on the spot, and that a steamer had to be sent for to England. The receipts on the Malta and Alexandria line have increased in a most remarkable manner. Thus, in the first quarter of 1862 the gross receipts, according to the returns communicated to Parliament, were £6,853; in the last quarter of that year they rose to £11,958; again, in 1863, the gross receipts were £12,047, and in the last quarter of that year they again rose to £21,560. This latter sum is at the rate of 20 per cent. upon the cost of the line (£436,000). The net receipts are not given in the returns, but we understand them to have been 16 to 17 per cent. in the most favourable quarter. Telegraphs connecting distant countries obliterate all competition on the part of the post-office, and are certain to be highly remunerative, the necessity and inducement for telegraphing in such cases being imperative.—*Malta Observer*.

The Telegraphic Treaty between Hamburg and Holstein.—The following is the exact text of the telegraphic treaty concluded between the city of Hamburg and the Federal Commissioners for the Duchy of Holstein, to which exception is said to have been taken by Prussia:—Treaty for the regulation of telegraphic communication of the free Hanse Town of Hamburg with the Duchy of Holstein, and over the frontiers thereof, as well as with Cuxhaven.—As in consequence of the negotiations which have taken place by order of the Senate of the free Hanse Towns of Hamburg and Lübeck and the Federal Commissioners for the Duchies of Holstein and Lauenburg upon the conclusion of a treaty for the establish-

ment of telegraphic communication with Hamburg and Lübeck through Holstein, it appeared desirable to regulate at the same time the telegraphic communication of the free Hanse Town of Hamburg with the Duchy of Holstein and over its frontiers, as well as with Cuxhaven; the negotiations appointed by the Senate of the free Hanse Town of Hamburg and the Federal Commissioners—viz., Syndic Dr. Carl Hermann Merck and Governmental Councillor Carl Ernst Emil Lesser, Member of the Ducal Government at Kiel, have agreed to and concluded the following treaty, reserving its approval by their respective superiors. Section 1. The free Hanse town of Hamburg undertakes the obligation of forwarding telegraphic messages coming from and by way of Hamburg, and destined for a northerly direction, upon the line existing between Hamburg and Altona or upon a new line to be constructed, and binds itself to permit the Ducal telegraph administration to forward messages destined for Hamburg, and distances past that city upon the line to be maintained by Hamburg between Hamburg and Altona and through the Hamburg telegraphic offices. 2. For the use of the wires upon the Ducal State telegraph lines the Hamburg telegraph station shall pay to the Ducal Telegraph Administration 50 per cent. of the gross receipts, calculated according to the tariff in operation upon the Ducal State telegraph lines. On the other hand, 10 per cent. will be returned to the town of Hamburg as compensation for the works it will have to undertake to join the Ducal lines. 3. Permission shall be given to the free Hanse Town of Hamburg to establish telegraphic communication between Hamburg and Cuxhaven by submerging a cable from Cuxhaven to Brunsbüttel, and making use of the poles of the West Holstein telegraph line to carry the requisite wires. The works necessary for this purpose upon the West Holstein telegraph line shall be carried on under the direction of the Holstein Telegraph Administration, the costs hereby entailed being defrayed by Hamburg upon presentation of the account, while the maintenance of the line will be undertaken by the Holstein Telegraph Administration upon its own territory. 4. Provided, upon nearer examination, some other point upon the Holstein coast—as, for instance, Neufeld —shall be thought better adapted for the landing-place of the cable from the district of Ritzebüttel, the free Hanse Town of Hamburg shall be at liberty to land the cable there, and carry a telegraphic line to Brunsbüttel. 5. The free town of Hamburg shall pay the Holstein Telegraph Administration, as compensation for the concessions in sections 3 and 4, 25 per cent. of the gross receipts derivable from the transmission of private messages between Cuxhaven and Hamburg, and *vice versâ*, along the Hamburg and Cuxhaven line through Brunsbüttel. 6. Should an extension of the line past Cuxhaven take place, the private messages sent along the line passing through Holstein shall be paid for by handing over 25 per cent. of the Hamburg share of the tariff for that line to the Holstein Telegraph Administration. 7. This treaty shall be concluded for the term of ten years, from the 1st January, 1865, and shall continue in force for terms of similar duration, so long as notice of its cessation shall not have been given by either party six months prior to the expiration of one of the decimal periods. 8. This treaty shall be prepared in duplicate, and the exchange of the ratifications take place within four weeks at latest from the present date. Done at Hamburg, this 22nd July, 1864. (Signed) C. H. MERCK; DR. E. LESSER.

MISCELLANEA.

MAGNESIUM.—We hear that one of the *soirées* of the British Association, at Bath, is to be lighted up during the whole evening with burning magnesium wire. It is also anticipated that several places of business and amusement in London and the country will be occasionally illuminated during the coming winter by the same means. A magnesium metal company has been formed in Manchester, and their works are now in active operation in Salford.

UNPERCEIVED AGENTS.—Let the reader sum up the influences that meet in the room where he sits with our paper in his hand. There in that room is, first, the atmospheric air, with its oxygen, azote, carbon, hydrogen, and various gases. There is the light, with its green, yellow, scarlet, violet, and various component elements. There is gravitation connecting that room with every orb of immensity, one cord of which binds it to the sun, another to the moon, another to the planets and satellites, and others still to the most distant stars which twinkle on the mantle of night. These cords of influence, meeting and twining into a complicated network, now pervade the very space where the reader peruses this article, thus connecting him, by invisible ties, to the whole framework of nature. There, besides, is electricity, magnetism, galvanism, and how many more agents we know not. An electrical machine would reveal electricity, a magnetic needle magnetism, and a galvanic battery galvanism. Yet none of these powerful agents around you make you sensible of their presence, except as you learn the fact by the discoveries of science. In the same room your mind exists, with its world of interests and sympathies, and the minds, perhaps, of your family and friends. Each one has in this same space the passions, hopes, fears, loves, hatreds, aspirations, revulsions, and all the elements of distinct organic and spiritual life. Still, the mind of each one is a sanctuary upon which the others cannot obtrude, except so far as he shall admit them to share the secrets of his bosom. Each one is also destined to an immortality of life; so that in this room where you are reading are beings whose hopes grasp the infinite realities of a life to come, and connect them with the throne of God.

LIGHTNING CONDUCTORS.—At the May meeting of the Franklin Institute, Pennsylvania, America, Mr. James D. Rice submitted for examination several forms of lightning rod points, and made the following remarks:— "A new invention is not claimed for any of the lightning rod points exhibited, but simply a modification of a point constructed by Professor Robert T. Hare. Through the kindness of Judge Hare I have obtained this point for exhibition this evening: at a future time it is to be presented to the Franklin Institute, to be deposited in their model-room. This point is constructed of eighteen small copper wires, soldered to the upper end of an iron rod, the junction surrounded by a zinc ball, the object of which is to preserve the copper points from oxidation. This point was made over thirty years ago—as I find it described in Professor Hare's Chemistry—and, as may be seen by examination, the copper wires are in good order. I exhibit two points of my own construction, differing somewhat from Professor Hare's, but upon the same principle. One of these was placed upon a flag-pole upon the American Mechanics' Hall, and was struck by lightning last summer; one of the copper points shows slight marks of fusion, but not injured for further use; no other effects could be traced upon the rod or building. Here is another point which has been struck, a platina point, of M'Allister's manufacture; the platina is all melted off, and the rest of the points much torn by the explosion. This I have found to be the case in all instances with the platina point, doubtless owing to its very low conducting power and the form in which it is used. Another objection to this point is the very imperfect method of connecting the point to the rod. I consider the platina points of little value for lightning rods. Points should be so constructed as to be uninjured when repeatedly struck. In replying to the remarks of Professor Frazer, my opinion is, that although lightning conductors in complete order do silently convey electricity from a cloud, yet they cannot in this way prevent a stroke at all times; if they could, lightning should never strike in this city where there are many hundred rods, many of which are as complete as possible, and yet it does strike from three to six times or more every season. Again, whoever has watched the lightning's flash during storms, has observed it to pass horizontally a long distance—probably many miles—and then descend to the earth; in such cases, the clouds being too far off to be discharged silently by the conductor, it then becomes the office of the lightning rod to receive and convey the stroke harmlessly into the earth. In an instant it may pass from the clouds, say ten or fifteen miles distant, to one directly over us, and thence to the earth, destroying life and property without discrimination, unless protected by suitable conductors. A word or two relative to insulation of rods; no good authority sanctions their use. Professor Hare's rod, erected by himself, on the contrary, is soldered to the metal roof, making the roof a part of the conductor. This principle I have adopted on many large buildings in this city, such as railroad depôts, market-houses, Girard College buildings, &c."

THE SUBSTITUTE FOR GUTTA-PERCHA.—Our readers are aware that the Society of Arts recently awarded its gold medal to Sir William Holmes for his introduction of balata into British commerce. The history of this gum, or vegetable milk, points to Mr. Charles Hancock as the first to recognise its valuable properties, and to recommend its employment as a substitute for india-rubber and gutta-percha, as will be seen by the following letter of Sir William Holmes to P. Le Neve Foster, Esq. In this instance, as in others that have come under our notice, the wisest discrimination has not been exercised by the Society of Arts in its award:—"I was Commissioner, representing the colony of British Guiana, at the International Exhibition of 1862. Amongst the varied contributions from the colony was a morsel of the dried milk of the bullet-tree (*sapota mulleri*); it weighed, perhaps, half a pound. Amongst the numerous individuals who visited the Guiana department was Mr. Charles Hancock, who is well known in the gutta-percha trade. This gentleman was struck with the appearance of the specimen, and obtained a portion for experiment; he reported favourably as to its utility and value, a result most gratifying to me, as I had received adverse opinions from less experienced persons. This happened, I think, in July, 1862. From that time to the present I have been engaged in investigations how to produce the material cheaply, and how to dry or coagulate it rapidly. In both particulars I believe I have succeeded so far as to warrant the importation of steam machinery to be applied to its extraction, and by a fortunate accident I have discovered how to dry or coagulate it, preserving the characteristic of elasticity at a single operation by the addition of a simple ingredient not very costly. The samples forwarded consist of—1st, a bottle of milk, as extracted from the tree by tapping; 2nd, of lumps or cakes, weighing together five pounds, of this milk prepared for the market; and 3rd, some balls to show, by the result of the process discovered by me, that this material is nearly as elastic as india-rubber; indeed, as far as I can judge, balata cannot be rivalled by either that material or gutta-percha, possessing, as I before stated, much of the elasticity of the one and the ductility of the other, without the intractability of india-rubber or the brittleness and friability of gutta-percha. Amongst the useful properties possessed by balata, I believe the fresh milk of the bullet-tree to be the best waterproofing material yet discovered; and further, that balata, as prepared by me, will supply the great want of the day, as a good insulating medium for telegraphic purposes. The bullet-tree is a magnificent timber tree, often squaring thirty to forty inches, and is much used, especially in Berbice, for building purposes. The milk, when quite fresh, is so bland that it is sometimes used as a substitute for cow's milk, and the fruit is delicious. The bullet-tree abounds in many districts

of the colony—indeed, I may say throughout this part of South America; and I trust that balata may ere long be added as an important item to the exports of the colony, and tend to prove that the International Exhibition of 1862 has, in this instance also, been productive of practically useful results, not only to this community, but to the interests of science and art generally."

Nothing New under the Sun.—Great inventions do not spring into existence in a state of perfection, and hence there is some pertinence in the words of Solomon, "There is no new thing under the sun," in their frequent application by those disposed to detract from the merits of the ingenious men who have invented or perfected the most important elements of our modern civilization. The beginning of most inventions is very remote. The first idea born within some unknown brain passes thence into others, and at last comes forth complete, after a parturition it may be, of centuries. One starts the idea, another develops it, and so on progressively, until at last it is elaborated, and worked out in practice. It is not possible to measure the share of each in the merit of the invention, and apportion it duly, but mankind is most indebted to him who gives it vitality and practical utility. Sometimes a great original mind strikes upon some new vein of hidden power, and gives a powerful impulse to the inventive faculties of man, which lasts through generations. More frequently, however, inventions are not entirely new, but based upon contrivances previously known. Glancing back over the history of the useful arts, we occasionally see an invention seemingly full-born, when suddenly it drops out of sight, and we hear no more of it for centuries. It is taken up anew by some inventor, stimulated by the needs of his time, and falling again upon the track, he recovers the old footmarks, follows them up and completes the work. The history of the steam engine is now to a certain extent familiar to most reading men, and the progress of its invention can be traced at intervals through a period of over 2,200 years. An old German book, printed in the year 1577, speaks of the reaping machine as a worn-out invention which was wont to be used in France, and the description therein contained shows it to have been, at least, somewhat like the modern machines for the same purpose. Breech-loading cannon and firearms, made at least 300 years ago, and revolvers 200 years old, are now in existence. Anæsthetics were used by the ancient Egyptians. Something like the daguerreotype, printed by the light of the sun, was known to Leonardo da Vinci 400 years ago. The idea of propelling vessels by steam seems to have been experimented upon by Blasco de Garay, as early as the year 1543. The conception of the electric telegraph dates back over 200 years. The use of coal gas, for lighting purposes, was known to the Chinese many years before it was known in Europe and America, and something like the modern postage stamp is said to have been used in Paris in the year 1653. Yet, in view of these facts, no candid mind will refuse to acknowledge Watt as the inventor of the condensing steam-engine and the most important feature of the high-pressure engine, as we now know and use them, or grudge the honour due, and, by common consent accorded to Fulton, McCormick, Colt, Daguerre, Morse, Murdock, and other great inventors now living or but recently passed away, for their labours in developing and perfecting the machines, processes, and contrivances which have now become the very essentials of civilized life. He is most essentially the true inventor who gives practicability to ideas, whether they have originated in his own brain or in the minds of others.—*American Artizan.*

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2020. G. Bedson, improvements in "spinning" or twisting wire for fencing and other purposes.

2023. J. Dilkes and E. Turner, improvements in apparatus for facilitating communications between passengers, guards, and drivers, travelling by railway trains.

2029. S. Moore, improvements in electro-gilding.

2035. T. Morgan, improved means of communication in railway trains between passenger and guard, and guard and engine-driver, or otherwise.

2038. W. Milligan, an apparatus for communicating motion from one railway carriage to another, in a train applicable for signalling between passengers, guard, and driver, fastening and unfastening the carriage doors, working the breaks, and other purposes.

2045. T. Turner, improvements in communicating between one part of a railway train and another part thereof.

2047. T. P. Tregaskis, the improved use of magnets in overbalancing weights.

2049. W. Clark, improvements in apparatus for transmitting motion and power from one part of a railway train to another, for the purpose of effecting communication between the passengers and guard or otherwise, and for operating the breaks.—A communication.

1852. C. Cotton, improvements in railway carriages, to facilitate the communication of passengers from carriage to carriage of a railway train.

1853. W. Thomas, improvements in effecting communication between passengers and guard, and guard or other person in charge of railway trains.

2063. J. Thomsen, improvements in batteries for generating electricity, and in apparatus for converting the quantity thereof into intensity.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1820. W. Booth, an improved means or method of communication between the guards, passengers, and engine-drivers of railway trains, or other public conveyances to which the same may be applicable.

1868. W. Dicey, an improved means of communication between railway guards or other attendants and passengers in railway trains.

1906. E. Tattersall, improvements in effecting communications in railway trains between passengers and guards.

PATENTS SEALED.

1242. J. Hamilton, jun., improvements in electric telegraph posts.

1565. J. D. Adams, improvements in electrical communicators.—A communication.

PATENT WHICH HAS BECOME VOID.

1967. L. W. Voillier, improvements in machinery for doubling and twisting yarns and threads, and for manufacturing wire rope.—A communication.

NOTICES TO PROCEED.

893. J. H. Simpson, certain improvements in printing from type by electricity.

996. H. Wadkin, improvements in apparatus for working points and signals of railways.

1820. W. Booth, an improved means or method of communication between the guards, passengers, and engine-drivers of railway trains, or other public conveyances to which the same may be applicable.

1853. G. Lansdown, a method of providing a direct communication between any guard and any passenger in a railway train.

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

2069. S. Whitaker and R. A. Jones, improvements in operating upon railway signals, and in indicating their position by means of electricity. 20th August, 1861.

PRICES CURRENT OF INSULATING MATERIAL.

ELECTRO-METALLURGY BY INDUCTION.

Last week, in speaking of experiments made with Mr. Thompson's induction machine, we stated that it was intended to make some experiments with it in electro-deposit or electro-plating. Since then a series of experiments has been begun, of which we can speak of one. In the ordinary electro-depositing generally one large vat is used, and battery cells of enormous size and few in number; therefore this deposit is by electricity of low intensity. If the resistance of the vat be not properly balanced with the intensity of the battery, the electro-deposit is irregular; either the metal is thrown down as (what is termed by electro-platers) metallic mud, or else the process lags and is almost brought to a standstill. The former takes place when the resistance is less than the power of the battery. The latter when it is more. In some cases even, if the metal is not thrown down in the shape of mud, it is deposited on the surface that has to receive it, in a rough and lumpy state; therefore great care has to be taken that too great a quantity of electricity is not sent through the depositing vat. Then care has to be taken that a pellicle of oxide does not spread over the positive plates and articles in the vat, or there will be too great a resistance and the deposit will stop. The plates and articles have frequently to be taken out and cleaned: otherwise if the oxide be left on the article the subsequent metallic deposit will peel off. These are all inconveniences incident to the practice of depositing by means of electricity of low intensity, and hitherto to use electricity of moderately high intensity required batteries of a considerable series of cells, which introduce a trouble of another kind: the trouble of keeping large batteries in order. With this machine this difficulty is overcome, but the procedure is somewhat different. Instead of a large vat a series of depositing cells is required. In this experiment fifty depositing cells were used; in each a surface of thirty inches was exposed. Besides these fifty cells the machine required to give it full work, an external resistance equal to the resistance of 20 miles of No. 8 iron wire, and the resistance of these 50 cells was under one mile of such wire; therefore the machine would have deposited in each of one thousand cells the same amount of metal as it deposited in each of the fifty. The quantity deposited in five hours in each cell was $3\frac{3}{4}$ grs., and thus for 1000 cells is 3750 grs., and for one day of ten hours 7500 grs., which is more than 1 lb. avoirdupois. And this deposit was in copper; in silver it would have been considerably more: the equivalent of silver being 108, while that of copper is only 31·7.

This process of electro-plating seems admirably adapted to the electro-plating of spoons and forks, and these are certainly articles wherein the greatest demand is.

From this experiment it appears that more than 200 dozen of spoons and forks could be electro-plated at once and in one day. Besides, no amount of oxide that can form on the positive plates prevents the flow of the electricity, and on the negative there was no oxide. The electro-deposit is perfectly steady and continuous throughout; there is no variation, so that if you ascertain how much is deposited in any one hour you will find the same deposited in any other hour; besides it is only necessary to ascertain what is deposited in one cell, for in each cell precisely the same quantity is deposited, neither less nor more, the same current of electricity passing through all.

This is only the beginning of a series of experiments. We hope by-and-by to be able to state more on this matter; for it would seem that induced electricity bids fair to take the place of voltaic.

THE ADVANTAGE OF OCEAN TELEGRAPHY.

The history of the first attempt to construct and submerge a deep sea line of telegraph between England and America, is a highly interesting one, and by no means devoid of instruction. However brief the triumph, it established a momentous fact, as eternal as the great Atlantic itself, that beneath its tempestuous billows there was laid once upon a time *a way for the "lightning of thunder."* However heavy the expenditure, the sacrifice, and the amount of dissipated hopes, the Atlantic cable was nevertheless the pioneer in whose gigantic stride others have followed, and will again follow, until success shall have crowned the noble and glorious effort.

As an illustration of some of the practical and important services which a system of ocean telegraphy is capable of rendering in cases of emergency, the following interesting statement, made in evidence before the Government Telegraph Committee, will serve to exemplify.

It is the evidence of Mr. Saward, the indefatigable Secretary of the Atlantic Company:—"During the Indian rebellion it had been expected that it would have been necessary to recall further troops into England, for the purpose of sending them to India; amongst others an order had been sent to Montreal and Halifax respectively, for the 32nd and 69th regiments to come home. The order was a written one. The state of affairs in India meanwhile took a more favourable turn, and the war department considered that it was no longer necessary that those troops should return; in consequence of which two messages were sent through the Atlantic Telegraph Company's cable, one to Montreal and one to Halifax, giving orders to the commanding officers at those places not to send home those regiments. In answer to the remaining part of your question (Mr. Varley's), as to the expense saved, of course it would involve the expense of ships to bring those troops home, and subsequently ships to return them to the same place again; the outlay for that purpose certainly could not be estimated at much less than £40,000 to £50,000." Mr. Newall, the eminent telegraph contractor, in his evidence, further exemplifies the benefit, by repeating a statement made to him by the late Lord Lyons, "that in his (Lord Lyons') opinion, the telegraph cable between Varna and Balaklava lessened the duration of the war by two or three months, by affording the means of rapid communication with the Crimea."

We have thus on record that in two cases of great emergency, ocean telegraphy was the means of saving the public a large amount of treasure, and tended materially to mitigate the horrors of a protracted and sanguinary war.

At the present time, when the United States of America are engaged in a fierce and bloody strife, and each day fraught with ominous consequence, not only to their own well-being, but also to our commercial and manufacturing interests, and our toiling millions, how deeply to be deplored is the silence of that once active and peaceful messenger, which, in the warmth of its first lisping efforts, proclaimed—"Europe and America are united by telegraph. Glory to God in the highest; on earth peace, good will towards man."

A comprehensive system of deep sea telegraphs would be a most valuable acquisition to the preventive and defensive institutions of the country. It should be laid so deep as not to allow of its destruction by an enemy, so as to enable our military and naval authorities at all times to concentrate their whole forces at a given point, and to regulate the operations of those forces as completely and effectually as if they were under their own eyes.

In the matter of diplomacy, the advantage of rapid communication between distant countries it would be difficult to overstate; and it would be idle to suppose that the commercial world will long neglect the power which ocean telegraphy is capable of conferring on the commercial interests of various countries, by establishing them in closer contiguity as regards commercial intelligence and transactions; seeing that by it may be made known in the remote marts of America, India, China, and even Australia, and *vice versâ*, all the fluctuations in the prices of marketable commodities, and every bargain in stock or shares within a few minutes of the transaction being closed in either place. Further, the facility for social intercourse between families and friends permanently or temporarily sojourning in distant lands, which the telegraph would afford, is a subject which evokes the heartiest wishes for its success.

ON THE DIRECT CORRELATION OF MECHANICAL AND CHEMICAL FORCES.

By Henry Clifton Sorby, F.R.S.

Perhaps it may be thought somewhat strange that a geologist should undertake such a subject as the correlation of forces, but the very fact of my being a geologist has led to the investigation of which I now purpose to give a short preliminary account. In studying general chemical and physical geology, and especially in examining the microscopical structure of rocks, I have for a number of years been greatly perplexed with a class of facts which pointed both to a mechanical and to a chemical origin. At first I attributed them either to a mechanical or a chemical action, or to the two combined; but, in most cases, no satisfactory explanation could be given. At length, however, facts turned up which altogether precluded any supposition not involving direct correlation; for they most clearly indicated that mechanical force had been resolved into chemical action in the same way as, under other circumstances, it may be resolved into heat, electricity, or any other modification of force, as so ably described by Grove, in his work "On the Correlation of Physical Forces."

The effect of pressure on the solubility of salts has already been made the subject of speculation and experiment, and a considerable number of facts have been described, showing that pressure will more or less influence such chemical actions as are accompanied by an evolution of gas, so that it may cause a compound to be permanent which otherwise would be decomposed; but the results were for the most part so indefinite and unconnected, or of such a character, that Mr. Grove does not allude to the direct production of chemical action from mechanical force. That this is, however, extremely probable will be evident to all who have considered the manner in which the various physical forces are correlated; for if mechanical force can be produced by chemical action, why should not the converse be true? In this paper I shall endeavour to show that such is really the fact, and that in some cases the mechanical equivalent of the chemical force may be determined.

In order to obtain the necessary great pressure, I have made use of a modification of the method employed by Bunsen, but, instead of filling the tubes at the ordinary temperature of the atmosphere and then gently heating them for several hours, I, in the first instance, filled them at a temperature of 10° or 20° C. lower, so that when finally sealed up they contained considerably more liquid that they could hold without pressure at the ordinary temperature of the atmosphere at the time being, and thus, by its tendency to expand, this liquid and anything enclosed in the tube, were subjected to a very great pressure. By keeping the tubes in various parts of the house, according as the weather varied, I have been able to maintain for several weeks or even months a pressure of, for instance, about 100 atmospheres, as measured by means of a capillary-tube pressure-guage enclosed within the larger tube. Since, in all cases, I had a second tube, which from first to last was treated precisely like the other, pressure excepted, I have been able to determine the effect produced by the pressure with very considerable accuracy, at all events so as to leave no doubt whatever about the general facts. At the same time I wish it to be understood that the results described below must be looked upon only as approximations to the truth.

I will first call attention to the well-known influence of pressure on the fusing-point of various substances, since it is a connecting link between well-established facts and those I am about to describe. Bunsen and Hopkins have shown that substances which expand when fused, have their point of fusion raised by mechanical pressure; that is to say, since mechanical force must be overcome in melting, the tendency to melt must be increased by heat before that opposition can be overcome; and the pressure required to keep them solid at any temperature above their natural point of fusion may be looked upon as the mechanical presentative of the force with which they tend to fuse at that temperature. Professor W. Thomson has shown that, on the contrary, water, which expands in freezing, has its point of fusion lowered by pressure; that is to say, since mechanical force must be overcome in crystallizing, crystallization will not take place under increased pressure, unless the force of crystalline polarity be increased by reducing the temperature. Thus, calculating from his experiments, and from the known latent heat of ice, and assuming that no heat is gained or lost by contact with external objects, if we had one part of ice and 100 of water at 0° C., and then applied a pressure of 103 atmospheres, the ice would, as it were, dissolve in the water, the whole would become liquid, and the temperature be reduced to —·792° C., or, in other terms, at that temperature the tendency to crystallize is exactly counterbalanced by that pressure.

Now I find that similar principles held true with respect to the solubility of salts in water. If, when they dissolve, the total bulk increases, pressure reduces their solubility; whereas, if the bulk decreases, pressure makes them more soluble; in other words, solution or crystallization is impeded by pressure according as mechanical force must be overcome in dissolving or in crystallizing.

Various authors have written on the volume with which salts enter into solution; but since the subject before us requires a different class of facts to be taken into account, I shall base my conclusions on my own experiments. The volume with which salts exist when in solution, assuming that of the water to remain unchanged, varies greatly in the case of different salts, and also according to the amount in solution and the temperature. Thus, taking sal-ammoniac as an example, when there are 3 per cent. in solution in the volume is as if it expanded 3·40 per cent. on dissolving; whereas, when 25·55 per cent. are in solution, the expansion is 11·36 per cent., and when nearly concentrated at about 13° C., an additional quantity expands on dissolving 15·78 per cent. In by far the greater number of cases, however, there is a contraction on dissolving, and the amount gradually diminishes for each additional quantity entering into solution, so that the mean result is very different from what occurs when the solution is dilute or nearly saturated. It is this contraction or expansion when a small additional quantity is dissolved in a nearly concentrated solution that must be taken into account in the following calculations.

In determining the influence of pressure on the solution of salts, I found it requisite to adopt somewhat different methods according to the peculiarities of the salts. In some cases I sealed up in a saturated solution portions of the salt in clean solid crystals, and determined the effect due to pressure from their loss in weight; whereas in other cases I sealed up solutions containing more salt than could be dissolved at the temperature at which the experiments were made, and determined the effect of pressure from the difference in the weight of the crystals deposited, being of course careful to make allowance for any difference in the amount of solution in the tube with pressure and in that without, and to avoid any error that might be produced by a different temperature. In all cases I have had a tube with pressure and another without, treated from first to last in precisely the same manner, and kept exactly the same temperature, so that pressure was the only difference; and usually the effect was so well marked that there was no doubt about the result. In the case of chloride of sodium, solution goes on so slowly, and the mechanical equivalent of the force of crystallization is so great, that if pressure had been applied for only a few hours one might have concluded, with Bunsen, that pressure had no influence on solubility; but by maintaining it for a week or more, there was no difficulty whatever in perceiving that a solution which was quite

saturated without pressure dissolved more under a pressure of about 100 atmospheres.

The solubility of a salt in water appears to me to result from a kind of affinity which decreases in force as the amount of salt in solution increases. This affinity is opposed by the crystalline polarity of the salt; and when the two forces are equal, the solution is exactly saturated. As is well known, a change in temperature alters this equilibrium; and, according to my experiments, mechanical pressure relatively increases one or other of these opposing forces, according to the mechanical relations of the salt in dissolving. At all events, in the case of chloride of sodium the extra quantity dissolved under pressure varies directly with it for such pressures as glass tubes will resist, in the same manner as, according to Thomson's experiments, the fusing-point of ice is reduced. Thus I found that for a pressure of 49½ atmospheres the extra solubility was ·176 per cent., and for 121 atmospheres ·431, which are almost exactly in the same ratio. Hence, if s be the amount soluble without pressure, under a pressure of p atmospheres, the solubility at the same temperature would be $s + ps$, where the values of s and s are independent, and vary for different temperatures and different salts. Future experiments may perhaps show that this conclusion should be modified; but yet it will be well to adopt it provisionally, in order to compare together the mechanical relations of different salts which otherwise would not be so intelligible.

According to Michel and Krafft, and to Schiff, sal-ammoniac is the only salt known for certain to occupy more space in solution than when crystallized. Hence, under pressure mechanical force must be overcome in dissolving, and experiment shows that, on this account, the relative force of crystalline polarity is increased and the solubility decreased. This is the reverse of what results from an elevation of the temperature, so that the effect cannot be due to heat generated by the pressure, but must be the direct consequent of pressure. Calculating from an experiment where the pressure was 164 atmospheres, which gave a decreased solubility of 1·045 per cent. of the whole salt in solution, a pressure of 100 atmospheres would cause ·637 per cent. less to be dissolved than is soluble at 20° C. without pressure, and the pressure requisite to reduce the solubility to the extent of 1 per cent. would be 157 atmospheres. Expressing this fact in other words, we may say that a pressure of 157 atmospheres is the mechanical force with which the salt tends to dissolve in a solution containing 1 per cent. less than can dissolve at the same temperature without pressure, because the two forces exactly counterbalance one another. In a still more dilute solution the force would of course be still greater, in accordance with the fact of a greater pressure being necessary to prevent the salt from being dissolved. Supposing, then, that we had a solution a trifle more dilute than that just named, and in such indefinitely large quantity that a cubic inch of the salt could dissolve in it, and yet produce no sensible change in its strength, so that from first to last it might be considered to dissolve under a pressure of 157 atmospheres; and also, supposing that it was rigidly enclosed on all sides but one, so that the whole expansion must take place in one direction over an area of one square inch, since on dissolving there is an increase in bulk from 100 to 115·78, the solution of this cubic inch would, as it were, raise 2,355 lbs. through the space of ·1578 inch. This is mechanically the same as 371½ lbs. raised 1 foot, or, the specific gravity of the salt being 1·53, the same as 171 times the weight of the salt itself raised 1 metre. Since it involves no arbitrary unit but the metre, I shall adopt the last expression as the measure of the total amount of mechanical work done by the solution of salts which expand in dissolving, and which may conversely be looked upon as the measure of the mechanical force rendered latent, and, as it were, expanded in the act of crystallization when crystals are deposited. The value of this mechanical equivalent of course varies with the strength of the solution, as already remarked.

In the case of salts which occupy less space when dissolved than when solid, pressure, like the increased temperature, causes them to be more soluble; mechanical force is lost when they dissolve, and is, as it were, expended in giving rise to solution. When water thus containing more of a salt than could otherwise be dissolved at the same temperature is just saturated under any given pressure, the amount of pressure represents the force of crystalline polarity tending to cause the salt to be deposited in a crystalline form, but which is exactly counterbalanced by that pressure. I will not give the details for each salt, but subjoin a table of the results at which I have arrived for such as illustrate particular points of interest, the calculations being all made in accordance with the principles already described. I also give them in the case of water, calculated from Thomson's experiments, assuming that, when ice meets and mixes with water, it may be looked upon as dissolving in it; and, as will be seen, the mechanical force thus deduced is of the same general order of magnitude as that generated by the crystallization of salts:—

	I.	II.	III.	IV.	V.
1. Chloride of sodium	13·57	97	·407	·419	157
2. Sulphate of copper	4·83	60	1·910	8·183	7
3. Ferridcyanide of potassium. . .	2·51	86	·288	·335	42
4. Sulphate of potash	31·21	63	1·840	2·914	42
5. Ferrocyanide of potassium . . .	8·90	66	1·640	2·485	20
6. Water	8·93	—	—	·991	106

Nos. 2 and 5 are calculated as hydrated crystals.

Column I. gives the expansion of each salt in crystallizing from a nearly saturated solution of water, the volume in a crystalline state being taken at 100.

Column II. gives the actual pressure in atmospheres in the experiment.

Column III. gives the increased solubility due to the pressure given in column II., the total amount of salt dissolved without pressure being taken at 100.

Column IV. gives the increase in solubility that would be produced by a pressure of 100 atmospheres, as calculated in accordance with the principles already described, the same unit being taken as in column III.

Column V. gives the value of the mechanical work that could be done, or, so to speak, the amount of mechanical force set free when the various substances crystallized from a solution containing one per cent. more than would be dissolved without pressure, as measured by the number of times its own weight which any unit of the various salts could rise to the height of one metre in the act of crystallization. Conversely, it is the amount of mechanical force which becomes latent in the act of solution; and in the case of a still more supersaturated solution it would be greater, and *vice versâ*, in accordance with the fact of the increased solubility varying with the pressure.

On comparing together the various salts it will be seen that their properties vary very considerably. Thus, under the same pressure, the extra quantity of sulphate of copper dissolved is nearly ten times that of ferridcyanide of potassium. The mechanical equivalents also vary even more, being (for chloride of sodium) about 22½ times as great as for sulphate of copper. On the contrary, the mechanical equivalents of ferridcyanide of potassium and sulphate of potash are the same; but, under equal pressures, the extra quantity of the latter dissolved is nearly nine times as great, owing to the difference in the amount of expansion in crystallizing. This latter is, however, nearly the same for water and ferrocyanide of potassium, whilst, under the same pressure, the extra quantity of that salt dissolved is 2½ times that of ice, in consequence of the much greater mechanical equivalent of the ice. It appears to me that we may provisionally conclude that the increased solubility due to pressure varies directly with the change of volume, and inversely with the mechanical equivalent of the force of crystalline polarity, so that, if s be the total amount of salt which dissolves without pressure, c be some function of the change in volume in dissolving, and m some function of the mechanical equivalent of the force of crystalline polarity, the solubility, at the same temperature, under a pressure of p atmospheres, would be $+ s\frac{p.c}{m}$. If the salt be one that expands on dissolving, c of course is negative, and therefore under pressure the solubility becomes $s - \frac{p.c}{m}$; that is to say, it is diminished, as proved by experiment with sal-ammoniac. If no change in volume took place, we may, I think, also conclude that pressure would not in any way increase or decrease the solubility of salt. Moreover, since, when a solution is just saturated, the force with which the salt tends to crystallize is equal to that with which it tends to dissolve, their mechanical equivalents must be equal and opposite. Hence we may perhaps conclude that, other circumstances being the same, the mechanical equivalent of a salt like chloride of sodium, which so readily attracts moisture, would be greater than that of one like sulphate of copper, which so readily loses even its water of crystallization; and thus also the relative influence of equal amounts of pressure would be very different, as is confirmed by experiment in the case of these and some other salts.

The facts I have described, therefore, show that there is a direct correlation between mechanical force and the forces of crystallization and solution. According to some chemists, the latter is an instance of real combination; but, whatever views be entertained respecting its nature, we cannot, I think, deny that the force represents some modification of chemical affinity, or is at all events most closely allied to it. In comparison with some kinds of affinity it may indeed be, and probably is, weak; but yet, as I have shown, it sometimes has a very considerable mechanical equivalent, even when nearly counterbalanced by an opposite force; and since such pressures as glass tubes will resist have no very great influence on what we may perhaps consider a weak affinity, we cannot expect that any pressure at our command would have much influence on strong affinities. I have, however, succeeded in obtaining some results which apparently show that pressure influences undoubtedly chemical changes taking place slowly, and therefore probably due to weak, or nearly counterbalanced affinities.

The method adopted in this part of the inquiry was to seal up some solid substance in a solution which gives rise to a slow double decomposition, taking great care to have in the tube with pressure, and in that without, pieces cut so as to be of the same size and form, and a solution of the same character, so that, with the exception of pressure, all the conditions were the same. Possibly I may be so fortunate as to discover some case where the affinity is so weak that pressure may determine whether it go forward or not, of which fact the structure of metamorphic rocks furnishes examples; but hitherto I have only been able to prove that pressure modifies the *rate* at which chemical action takes place. This branch of the inquiry is, however, beset with many difficulties, for the change in volume produced by double decomposition is small, and its determination involves several complicated questions. The volumes of the solids is easily determined, but that of the salts in solution is not the same when other salts are present as when they are dissolved in pure water, and varies much according to the strength of the solution and the nature of the salts; and many points are still so obscure that I shall only give two cases by way of example.

When a portion of Witherite is enclosed in a tube with a strong solution of protochloride of iron, there is a slow decomposition into chloride of barium, which is dissolved, and carbonate of iron, which remains firmly attached to the Witherite, and would ultimately give rise to an excellent pseudomorph. The best conclusion at which I have been able to arrive is, that there is in the change an increase in volume equal to about 10·7 per cent. of the Witherite altered, so that, under pressure, mechanical force must be overcome. In an experiment where everything went on in a very satisfactory manner, the pressure was maintained for three months at from 80 to 100 atmospheres, and for one month was under 80 atmospheres, so that, on an average, it was about 80 atmospheres; and I found that the amount of chemical change was 21·7 per cent. less than when, all other circumstances having been the same, there had been no pressure; thus clearly showing that pressure had, as it were, diminished the force of chemical affinity. If then one cubic inch had been altered under this pressure, it would have overcome a mechanical force equal to that required to raise 1,200 lbs. through the space of ·107 inch, which is equivalent to raising twenty-one times its weight to the height of one metre; and under the same circumstances 1·278 cubic inch would have been altered when no such mechanical force had to be overcome. Supposing, then, that in both cases the total energy at work was the same, but in one was altogether expended in producing a chemical result, and in the other in producing partly a chemical and partly a mechanical effect, we may say that the force which gives rise to the purely chemical change, taking place at a particular rate, is equal to that which gives rise to this chemical effect, taking place at ·783 of that rate, and to a mechanical effect equal to the force required to raise in the same space of time 34·87 times the weight of the Witherite altered to the height of one metre. Supposing, also, that the power of chemical force varies at the rate at which it gives rise to a chemical change, in the same manner as the power of a mechanical force varies as the velocity of motion imparted by it, we may perhaps conclude that this mechanical force is equal to ·217 of the chemical force, and that the whole energy of the chemical action under the conditions of the experiment was equal to the mechanical power required to raise, in the same period of time, 160 times the weight of the Witherite altered to the weight of one metre. If these principles are correct, a pressure of more than 370 atmospheres would have entirely counterbalanced the force of chemical affinity, since to produce any chemical change it would then have had to overcome a greater force than it possessed. This is so great a pressure that I fear it will be difficult to prove the deduction by experiment; and until some such case can be found, capable of being verified, these calculations must be considered as little more than suggestions, which future investigations may confirm or disprove.

When calcite is sealed up in a mixed and rather strong solution of chloride of sodium and sulphate of copper, slow double decomposition gives rise to malachite, sulphate of lime, and carbonic acid; and though this is extremely complicated, and it is very difficult to determine what would be the change in volume, yet, so far as I am able to make out, until the solution becomes saturated with sulphate of lime, there is a decrease in volume equal to about 8 per cent. of that of the calcite altered, so that, under pressure, mechanical force is the very reverse of being opposed to the chemical change. Three experiments all indicate the same fact, and in which, on an average, the pressure was about ninety atmospheres for two weeks, show that, as a mean of the whole, the amount of chemical change of 17 per cent. more with the pressure than without; thus proving that pressure had, as it were, increased the force of chemical affinity. Calculating according to the principles described above, we may conclude that a pressure of 530 atmospheres would have caused the action to take place at double the rate, and that therefore the chemical action is equivalent to the expenditure of that amount of mechanical force, being thus generated by it. Arguing then in a manner similar to that already described, but modified to suit the different conditions, if there be a contraction equal to 8 per cent. of the bulk of the calcite, there must be a loss of mechanical force capable of raising twenty-eight times the weight of the calcite altered to the height of one metre, in the time required for the chemical change; which amount of mechanical energy, as it were, becomes latent, and is transformed into chemical action, and would again exhibit itself as a mechanical force if, by any means, the chemical affinities could be inverted, and everything restored to its original state.

In like manner, other experiments indicate that in some cases pressure causes a slower, and in others a quicker chemical action, whilst in others it has scarcely any influence whatever; and though, for reasons already explained, I say it with some hesitation, yet, bearing in mind what is already known respecting the action of pressure on hydrate of chlorine, hydrated hydrosulphuric acid, and other substances described by various authors, I think the facts I have described make it very probable that further research will show that pressure weakens or strengthens chemical affinity according as it acts against or in favour of the change in volume; as if chemical action were directly convertible into mechanical force, or mechanical force into chemical action, in definite equivalents, according to well-defined general laws, without its being necessary that they should be connected by means of heat or electricity. On the present occasion I shall not attempt to consider the various geological and mineralogical facts which appear to me to admit of the application of the principles I have described, for many of them are peculiarities in structure of which neither myself nor any one else has ever given a description, and would therefore demand a preliminary notice. However, I may say that it appears to me that a number of facts connected with metamorphic rocks and the phenomena of slaty cleavage, which, to me at all events, have hitherto been inexplicable, are readily explained if mechanical force be directly correlated to chemical action, and if in some cases the direction in which crystals are formed be more or less related to pressure, in some such way as there is a connection between their structure and the magnetic force shown by the experiments of Plücker, Faraday, Tyndall, and many other observers. We may also, I think, explain the origin of the impressions on the limestone pebbles in the "Nagelflue" in Switzerland, about which so much has been written in Germany and France, without a satisfactory reason having been discovered; and the same explanation accounts for the mutual penetration of the fragments of which some limestones are formed, and for the banded structure of some which possess slaty cleavage. The curious teeth-like projections with which one bed of limestone sometimes enters into another, also to a certain extent indicate a chemical action depending on mechanical force; and probably the same may be said of some of the peculiarities of slickensides and mineral veins. It is also possible that a pressure of several hundred atmospheres may facilitate some of the chemical changes involved in the transformation of water and carbonic acid into the organic compounds met with in animals and plants of low organization found at great depths in the ocean, and thus to a certain extent compensate for diminished light. I, however, most

willingly admit that very much remains to be learnt before we can say to what extent the principles I have described are applicable; and yet, at the same time, cannot but think that henceforth they must be taken into account in many departments of the chemical and physical geology, and will readily explain a number of facts which otherwise would be very obscure.

ADMIRAL FITZROY ON CHARTS, CURRENTS, &c.

FROM our synoptic charts, and other accumulated reasons, I now feel sure that the simply *mechanical* action of two (or more) air currents are the *immediate* causes of all our atmospheric motions, and that the antagonism of heat and cold occasion those currents—without electric *origination*—the development of electricity being *consequences* of the atmospheric *action*, excited by *cold* and *heat* (space and sun).

Incessantly as the earth turns, atmospheric currents are moved, and their normals are modified by circumstances, often varying. Oceans, mountains, deserts, forests, even rivers affect the winds in their course, progress, and nature.

Constant progression *toward* the west, in the intertropic zone, *must force* as incessant a movement of return towards the east, over, between, or under the perennial westward draught,—to equilibrate the fluid atmosphere, which is an almost generally concentric expanse of air—elastic, gaseous, infinitely mobile, chemically homogeneous, and *sensibly* not much exceeding ten or twelve miles in *depth*.

Each of the air currents acquires momentum, and each has obstacles in its progress. The effects of obstacles are not confined to their locality, but are carried elsewhere by the general movement.

Similarly, but on a merely microscopic scale, effects of rocks, piers, shoals, and vessels, are seen in a river, or tideway, where eddies, swells, lines of broken water, ripplings, or discoloration, are traceable to long distances from their causes.

All the variations and apparent anomalies of air currents, or winds, are remarkably like (though vastly more extensive and complicated, on account of elasticity, &c.), and, indeed, may be roughly illustrated, in explanation, by oceanic and fluvial movements.

In the temperate zone the chief currents of air run against, and over or under each other—one follows the retreat of its opponent, or presses onward (direct or deflected), as the other runs in a nearly opposite direction, at the same level.

When this last condition occurs horizontal eddies are caused, travelling between the juxta-pressing breadths of air (hundreds of miles in extent, possibly much more, often far less; but always very broad in proportion to depth) and carried along by them, for a very few days, or only hours. These cyclonic effects are near the principal points of meeting, or *nodes* of the main currents.

As one current fails, becomes less in velocity, quantity, or momentum, another increases; but not *immediately*. Time must elapse to admit of changed impulse, altering old and exciting new movements, in any direction. Once effected the result is seen in a flow (or wind) from the one place (that of most pressure or highest tension) toward the other, until a balance is restored.

Another remarkable and interesting mode of aerial action is when the main currents are so equably impelled and co-extensive that their antagonism is felt through many degrees of longitude at *nearly the same time*, and unusual commotion, with many combinations, result over an extensive area: some effects being like those described, others cyclonic; the whole, however, being carried *eastward* bodily, in accordance with the normal circulation of the atmosphere in temperate zones.

Lay a line (or rule) across a map of Europe, from Cape Clear to Toulon—it will lie N.W. and S.E., nearly (true). Imagine a parallel line extended each way from Cape Finisterre, and let this be supposed to represent the *average* advancing front of a S.W. wind, which, as it moves toward the N.E. (*over*, between, or here and there, even under the air *already* impelled along the surface toward the S.W.) *also* sides eastward? The resulting effects seem to be more rapid advance in *some places* than in others, through a space some 20 or 30 degrees wide, and a consequent protrusion of stream-like quantities into, or over, or under the polar current, considerably before the *whole front* has arrived. Such streams, opposed by polar air, recoil, or turn, or eddy—hence squalls, or even cyclones.

When a cyclone is thus caused, *or* by an actual lateral action of main bodies of air, it does not lose its impetus and momentum suddenly; but travels on between the parent bodies, impelled *more* northward *or even southward* of east—*according* as *either current* is the gaining, or advancing body—along earth's surface.

On the 1st, 2nd, 3rd and 5th of December, 1863, there were advancing bodies of air—each in great volume, and though their effects were very various—several characteristics were distinctly traceable. Owing to the *general* advance of one from north-east simultaneously with the other volume, or impulsion, from south-west—effects of a *similar nature* were felt all across southern and part of northern mid-Europe, say Ireland, Great Britain, Holland, Denmark, Germany, France, and Northern Italy.

But these effects were not due to *one travelling* cyclone—(monstrum horrendum!) they were results of two great atmospheric impulses—*seemingly*, not *truly* waves, but rather, as it were, pulsations from opposite directions, breasting each other in mutual opposition! When two such impulsions, however termed, are opposed to each other, or checked by any obstacle, they must swell or rise (if possible) or increase in *tension*. Their tendency (if unconfined) is to break against any impediment to their movements, and the results are horizontal currents. If the encounter is slow and *gradual*, vertical rise alone takes place, with increase of tension, checking any currents along the surface of earth. Of course currents already in motion act against each other similarly, with proportionate effect.

All our approaching south-westers appear to have a wave-like appulse—*aligning* from Cape Clear or Valentia, by Penzance, to Brest, and *further*, nearly at the same time. Now, if such an alignment crossing Finisterre—advances parallel to itself—it will touch Rochefort nearly with Valentia, and, allowing for *resistance* with some deflection by *land*, it may touch Marseilles, Toulon, &c., soon after—long before any cyclone could travel there *from* the *north-west*.

Complicated and difficult as the comprehension of all bearings of such cases of atmospheric commotion undoubtedly are, we must not be deterred from prosecuting them, or discouraged by quasi-uninformed men (on *these* subjects) saying, 'Meteorology is a mystery impossible to clear, and unsuitable for practical purposes." Dynamics—a careful observation of the movements of fluids in general, a full allowance for expansion of air, for its *resilience*, and when cooled for its *contraction*, for *deposit* of fog, dew, rain, hail, or snow, for heat, latent or otherwise, and for chemical changes, will gradually aid in developing all atmospheric questions.

While the principal currents are impelled against each other, or one over the other, atmospheric pressure (or tension) is augmented; and if equality continue, with gradual action alone, the result is a calm, with fine weather; but the contrary state or inequality—failure of one force—is directly followed by motion and its immediate results.

Among these *results* I now venture to place electric action—"*heat, a mode of motion*."

Electricity produced or excited in *common air*, even in a room, causes drops of water to fall, or will make a breeze.

Electricity is developed by the *frictional* action of *steam*—even *gas!* as shown at various institutions—especially the Polytechnic.

THE RAILWAY TELEGRAPH AT FAULT.

WE have been taken to task by more than one provincial paper for questioning the infallibility of the communication by electric telegraph on railways. We are admonished that Colonel Yolland's reliance is not misplaced, for that mistakes are quite unknown. We have cited one undeniable instance of fatal error, and we have not a doubt that many others occur which pass unnoticed because unattended with disaster. But only a few days ago there appeared in the *Times* an account of an accident caused by a mistake either in the wording or the understanding of a telegraphic message, with a reference to another error of the same class attended with fatal consequences:—

"An accident happened on the Shrewsbury and Hereford Railway a few days since, particulars of which have hitherto not been made public through the newspapers. It appears that some new rails were being laid down on a portion of the road between Ludlow and Shrewsbury, and here, the metals not being made quite tight, when a goods train came up it ran off the rails, obstructing the line. In consequence a passenger train which followed had to turn off the proper line at this point, and continue its journey on the other line of rails. Warning of its approach was signalled along the line, but from some mistake in the telegraphic despatch it was misunderstood, and the train on the wrong line had not proceeded

far when it met another train. The driver shut off steam, but a collision was unavoidable. Both drivers jumped off their engines, and escaped with a few bruises, but one of the stokers was much hurt, and both lines were obstructed for a considerable time. The up-mail train was hindered two hours. It will be remembered that a similar accident to this happened on the South Wales Railway between Pyle and Port Talbot three or four years ago, when, owing to an obstruction on the line by the breaking down of a cattle train, a passenger train was sent along the wrong line of rails, and met a second passenger train, two persons being killed and several persons seriously injured. In this case the telegraph had been used, and the line was supposed to be kept clear between Pyle and Port Talbot for the down train to proceed on the wrong line of rails. The message, however, was misunderstood, and the telegraph clerk was afterwards tried for manslaughter and sentenced to imprisonment."

Surely these, and many other instances that could be adduced, are enough to prove the fallibility of the telegraph for warning of danger on railways. And the liability to error is not confined to the clerk who sends the message, but extends to the servant who receives it, and conveys it to the signalman, with whom there lies a third chance of mistake. This is not a reason for not using the telegraph, but for not putting implicit trust in it. Let it be regarded as highly serviceable, but not infallible, and it will be conducive to safety and convenience without risk.

The greater the reliance on signals the greater is the danger of the public. It is relying on signals that railway managers despatch trains in the rapid succession which has caused so many collisions attended with destruction of life and terrible injuries. And every fancied improvement in signalling encourages the imprudence.—*Examiner.*

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

VI.

A.D. 1785.—M. Haüy, in 1785, knew the electric properties of calamine and of sphene, as developed by heat. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 133, 134.)

A.D. 1786.—Mr. Bennet, in 1786, by his electroscope, discovered the electricity developed by sifting powders. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 122.)

A.D. 1787.—Mr. Bennet, in 1787, first noticed that electricity was developed during the separation of the particles of bodies. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 138.)

A.D. 1787.—M. Haüy, in 1787, made the following discoveries:—That electricity is developed by heat in the minerals *mesotype* and *prehnite;* and that Iceland spar and some other crystals become electric by pressure. He also established many of the laws of pyro-electricity. (See Haüy's *Minéralogie*, Vol. II., p. 604; also *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 132, 133, and 138, 139.)

A.D. 1787.—Mr. Brard, about 1787, remarked that some crystals of axinite become electric by heat. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 132.)

A.D. 1787.—Lomond, in 1787, in an electric telegraph, employed one wire and a pith-ball electrometer. (See Highton's *Electric Telegraph*, pp. 38 and 41.)

A.D. 1787.—Betancourt, in 1787, used a telegraphic arrangement of one line wire and a battery of Leyden jars. (See Highton's *Electric Telegraph*, p. 38, and 41, 42.)

A.D. 1788.—Cavallo, about 1788, made known his condenser and other similar improvements. Other "condensers," "multipliers," and "doublers," were invented about this period. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, p. 91.)

A.D. 1788.—The Abbé Barthelémy "is said to have suggested an electric telegraph in his well-known work 'Voyage du Jeune Anacharsis," which appeared in 1788." This fanciful idea is as follows:—Two clocks were to have similarly magnetized hands; artificial magnets were presumed to be so far improved that they could convey their directive power to a distance; thus, by the sympathetic movements of the hands or needles in connection with a dial alphabet, communications between distant friends could be carried on. (See Mr. Macgregor's letter in the *Society of Arts Journal*, May 20, 1859, pp. 472, 473.)

A.D. 1790.—MM. Fourcroy, Vanquelin, and Seguin's grand experiment of the composition of water from its constituent gases was commenced on May 13, 1790, and continued without intermission until its finish on the 22nd of the same month. The gases were fired in a close vessel by means of electricity, and produced a nearly equal weight of water. (See Ure's *Dictionary of Chemistry;* also Noad's *Lectures on Chemistry*, p. 183, 184.)

A.D. 1790.—Paetz and Van Troostwik, in 1790, decomposed water into its constituent gases by passing the electric spark through it, very fine gold wires being used as electrodes. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 443.)

A.D. 1791.—Haüy, in 1791, discovered the electrical properties developed in borate of magnesia (boracite) by heat. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 131, 132.)

A.D. 1791.—Galvani, in 1791, found that the limbs of a frog were convulsed when his pupil touched them with a dissecting-knife at the same time that a spark was drawn from the prime conductor of an electrical machine. He afterwards found that similar convulsions were produced by establishing a communication between the nerves and muscles by means of metals; thus laying the foundation from which the galvanic battery afterwards sprung, also of the science of animal electricity. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 220; also Bakewell's *Electric Science*, pp. 27-29; also De la Rive's *Treatise on Electricity*, Vol I., pp. 29, 30, Vol. II., pp. 483 and 488, 489, and Vol. III., pp. 3-6.)

A.D. 1791.—Keir, in 1791, knew that iron and other metals could be made "passive" or electro-negative, so as not to be soluble in acids. (See Gmelin's *Handbook of Chemistry*, Vol. I., p. 353.)

A.D. 1793.—Dr. Fowler, in 1793, made a great number of experiments on the effects of galvanism in different animals, and on different parts of animals. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 220.)

A.D. 1793.—Volta, in 1793, in a letter to Cavallo, laid the foundation of the contact theory of galvanism. (See *Philosophical Transactions*, 1793; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 220.)

A.D. 1794.—Reizen, in 1794, had an electric telegraph of 26 line wires; the letters of the alphabet were cut out in pieces of tinfoil, and rendered visible by sparks of electricity. (See Highton's *Electric Telegraph*, pp. 38 and 42, 43.)

A.D. 1795.—Cavallo, in 1795, used an electric telegraph with one wire; the number of sparks was made to designate the various signals, and the explosion of gas was used for an alarum. (See Cavallo's *Traité de Télégraphie Electrique*, 4th edition, Vol. III., p. 285; also Abbe Moigno's *Traité de Télégraphie Electrique*, p. 61; also Highton's *Electric Telegraph*, pp. 38 and 43.)

A.D. 1795.—Dr. Wells, in 1795, found that charcoal may be employed to excite the galvanic influence, and that it is a conductor of that influence. He supposed galvanism and electricity to be identical. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 220, 221.)

A.D. 1796.—Salva, in 1796, invented an electric telegraph, the exact particulars of which are unknown. (See Highton's *Electric Telegraph*, pp. 38 and 43, 44.)

A.D. 1796.—Adini, about 1796, produced, by galvanism, powerful muscular contractions upon the head of an ox recently killed. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 489.)

A.D. 1797.—Nicholson's spinning condenser was made known in "Nicholson's Journal" of April, 1797. Hooks connected to tinfoil mounted suitably on glass planes, one of which revolves while the other is quiescent, conduct the charges successively derived from the electrified body to electroscopic balls; a rotation given by the finger and thumb thus enables an exceedingly small charge of electricity to be detected and examined. By means of this instrument, Messrs. Nicholson and Carlisle ascertained the nature of the electricity of the ends of the composite galvanic battery. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 90, 91, and art. Galvanism, p. 177.)

A.D. 1799.—Fabroni, in 1799, "enters into an inquiry whether the phenomena of galvanism may not originate from the action of chemical affinities, of which electricity may be one of the concomitant effects." (See *Journal de Physique*, xlix, 348; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 215, 216.)

A.D. 1800.—Volta, on the 20th of March, 1800, "addressed a letter to Sir Joseph Banks, then President of the Royal Society, in which he announced to him the discovery of 'the voltaic pile;'" this letter was read before the Royal Society on June 26, 1800; the arrangement used consisted of discs of silver, zinc, and moistened card, placed in series. "La Couronne de Tasses" was afterwards invented by Volta; this arrangement consisted of a circle of cups,

each cup containing solution of salt, silver, and zinc, thus forming a perfect voltaic or galvanic battery. (See Bakewell's *Electric Science*, pp. 29, 30; also Highton's *Electric Telegraph*, p. 13.)

A.D. 1800.—Messrs. Nicholson and Carlisle, on the 2nd of May, 1800, decomposed water by the voltaic pile. They constructed a voltaic pile by means of the particulars given in the first four pages of Volta's letter, Sir Joseph Banks having, at the end of April, shown this part of the communication to Sir Anthony (then Mr.) Carlisle. (See Highton's *Electric Telegraph*, pp. 27-29.)

A.D. 1800.—Mr. Cruickshank, in 1800, arranged metallic plates and a liquid according to the principle of Volta's pile, but horizontally in a trough instead of vertically, the plates themselves forming the cells. He also changed the colour of litmus paper by the galvanic current. (See Highton's *Electric Telegraph*, pp. 13, 14, and 29.)

A.D. 1800.—Dr. Henry, of Manchester, about the year 1800, by the galvanic battery, decomposed the nitric and sulphuric acids and resolved ammonia into its elementary constituents. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 221, and art. Chemistry, p. 611.)

A.D. 1801.—Dr. Wollaston, in 1801, used ordinary frictional electricity to decompose water by means of his guarded poles. These poles were made by fusing the end of a capillary tube round a gold wire, and grinding the tube down gradually until the least possible portion of the wire was exposed; he was thus able to transmit the power of the electrical machine as a continuous current. (See De la Rive's *Treatise on Electricity*, pp. 444, 445.)

A.D. 1801.—Dr. Wollaston, in 1801, "decidedly pronounced that the oxidation of the metal in the pile is the primary cause of its electrical effects." (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 216.)

A.D. 1801.—Gerboin, in 1801, pointed out certain movements of mercury in an inverted syphon, beneath the positive pole of a galvanic battery, the said pole being immersed in an electrolytic solution, which covers the surface of the mercury, and the other pole of the battery being connected to the mercury in the other leg of the syphon. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 433.)

A.D. 1802.—A contributor to the Monthly Magazine for April, 1802, says that "Galvanism is at present a subject of occupation of all the German philosophers and chemists. At Vienna an important discovery has been announced—an *artificial magnet*, employed instead of Volta's pile, decomposes water equally well as that pile or the electrical machine, whence it has been concluded that the *electric*, *galvanic*, and *magnetic* fluids are the same." This announcement is of interest in respect to magneto-electricity. (See Bakewell's *Electric Science*, p. 40.)

A.D. 1803.—Trommsdorff, about the year 1803, discovered the efficacy of large plates, in galvanic batteries, in producing combustion of thin metallic leaves. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 221.)

A.D. 1803.—Hisinger and Berzelius, in 1803, "ascertained, by a numerous series of experiments, the transfer of the elements of water and of neutral salts to the respective poles of the battery." (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 221, 222; also *Gehlen's Journal*, Vol. I., 1803.)

A.D. 1803.—Mr. Carpue, in 1803, published some noteworthy experiments on the therapeutic action of common electricity. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electricity, pp. 105, 106.)

A.D. 1803.—M. Thillaye gave, in 1803, a great number of useful precepts on the medical application of ordinary electricity. He used electric brushes, held by an insulated handle and put into communication with the conductor of the machine. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 587, 588.)

A.D. 1803.—Aldini, in 1803, sent a galvanic current through the body of a criminal executed at Newgate. The most violent agitations and muscular contractions were produced. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 196, 197, and 221.)

A.D. 1803.—Mr. Dyekhoff, about 1803, made a dry electric column. (See Sturgeon's *Lectures on Galvanism*, p. 73.)

A.D. 1805.—Behrens, in 1805, constructed a dry pile of 80 pairs of zinc, copper, and gilded paper. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 852.)

A.D. 1805.—Romagnési, a physician of Trente, about the year 1805, observed that the magnetized needle "experiences a declination," when submitted to the action of the galvanic current. (See *Manuel du Galvanisme*, par Joseph Izarn, Paris, 1805, p. 120; also *Journal of the Society of Arts*, April 23, 1858, p. 356.)

A.D. 1805.—M. Mojon, a chemist of Gènes, about the year 1805, observed that unmagnetized needles, when submitted to the action of the galvanic current, "acquire, by this means, a kind of magnetic polarity." (See *Manuel du Galvanisme*, par Joseph Izarn, Paris, 1805, p. 120; also *Journal of the Society of Arts*, April 23, 1858, p. 356.)

A.D. 1805.—Brugnatelli, in 1805, "gilt in a complete manner two large silver medals, by bringing them into communication by means of a steel wire, with the negative pole of a voltaic pile, and keeping them one after the other immersed in ammoniuret of gold, newly made and well saturated." (See Smee's *Electro-metallurgy*, History, pp. 25, 26; also a letter from Brugnatelli to Van Mons in the *Philosophical Magazine*, 1805.)

A.D. 1807.—Sir Humphrey Davy, on October 6th, 1807, made his celebrated discovery of the compound nature of the alkalies. By means of a battery power of 274 pairs of plates, he decomposed potash, and found that potassium was formed on the application of galvanic power to a piece of moistened potash. Sir Humphrey's delight on this memorable occasion was excessive; on seeing the globules of potassium burst through the crust of the potash, and take fire as they entered the atmosphere, he could not contain his joy, and some time was required for him to compose himself sufficiently to continue the experiment. (See Noad's *Lectures on Chemistry*, pp. 32, 33; also Bakewell's *Electric Science*, pp. 33-35.)

A.D. 1808.—Napoleon, in 1808, presented a trough galvanic battery of 600 pairs of plates to the Polytechnic School at Paris. (See Lardner's *Handbook of Natural Philosophy*, Voltaic Electricity, p. 116.)

A.D. 1809.—Soemmering's telegraph was invented in 1809. In "this telegraph galvanic electricity was used, and as many wires were employed as there were letters or signals to be denoted. The letters were designated by the decomposition of water; an alarm was also added." (See Highton's *Electric Telegraph*, p. 39; also *Journal of the Society of Arts*, May 13, 1859, p. 453.)

A.D. 1809.—Mr. Childern, in 1809, formed a very large and powerful galvanic battery, upon the principle of Volta's *Couronne de Tasses*. The most refractory substances were fused by it, such as platinum (a bar one-sixth of an inch square), the oxides of molybdenum, tungsten, uranium, titanium, cerium, and tantalium, the compound ore of iridium and osmium, also diamond, blue spinell, gadolinite, and zircon; ruby, sapphire, quartz, and silex, were not affected. (See *Philosophical Transactions*, 1815, pp. 368-370; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 179, 222.)

A.D. 1810.—Coxe's telegraph was invented in 1810; he "proposed the use both of the decomposition of water and also of metallic salts." (See Highton's *Electric Telegraph*, p. 39.)

A.D. 1810.—De Luc, in 1810, made a "dry" pile of tinned iron and gilded paper. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 852.)

A.D. 1812.—Schilling, in 1812, proposed to blow up mines by galvanism. He ignited the powder by means of pieces of charcoal, and invented an "electro-conducting cord" to convey the electric fluid to the desired locality. (See *Journal of the Society of Arts*, July 22, 1859, p. 598.)

A.D. 1812.—Samboni, in 1812, constructed a dry pile of paper discs, covered on one side with tin and on the other with peroxide of manganese. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 852.)

A.D. 1812.—Ritter, about the year 1812, constructed his "secondary pile." This instrument consists of alternate discs of copper and moistened card, and is capable of receiving a charge from a voltaic pile, and of thence producing the physical, chemical, physiological effects obtained from the ordinary pile. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 206.)

A.D. 1813.—Sir Humphrey Davy, about the year 1813, discovered the convective discharge between charcoal or carbon electrodes, called "the voltaic arc." The galvanic battery of the Royal Institution, consisting of 2,000 pairs of zinc and copper, each having a surface of 32 square inches, and charged with acidulated water, was used to produce this phenomenon. The discharge took place through more than 4 inches of air, and 6 or 7 inches of vacuous space. "When any substance was introduced into this arc, it became incandescent; platinum melted in it like wax in the flame of a candle; sapphire, magnesia, lime—all the most refractory substances—entered into fusion. Fragments of diamond, points of carbon and of plumbago, disappeared rapidly, and seemed to evaporate in this focus, without appearing to undergo previous fusion." (See Davy's *Elements of Chemical Philosophy*, pp. 152-

154; also De la Rive's *Treatise on Electricity*, Vol. II., pp. 282, 283; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 176, 178, and 222.)

A.D. 1813.—Mr. J. R. Sharpe, of Doe Hill, near Alfretton, early in February, 1813, "devised a *voltaic* electric telegraph, which he exhibited to the Lords of the Admiralty, who spoke approvingly of it, but added, that as the war was over, and money scarce, they could not carry it into effect." (See *Repertory of Arts*, 2nd series, Vol. XXIX., p. 23; also *Saturday Review*, August 21, 1858, p. 190.)

A.D. 1815.—Dr. Wollaston, in 1815, invented his galvanic battery. Dilute sulphuric acid was the exciting solution; a plate of copper was placed on each side of the zinc, and the whole was arranged in a trough composed of a number of cells. By attaching the plates to a rod, the whole of them might be lifted out of the liquid at once. (See Highton's *Electric Telegraph*, p. 14.)

A.D. 1815.—Wollaston's celebrated thimble battery apparatus was constructed in 1815. It consisted of a flattened silver thimble, in which a zinc plate was fixed by sealing wax. This galvanic battery ignited a fine platinum wire by immersion in an aqueous solution of only one-fiftieth part of sulphuric acid. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 180, 181, and 222.)

THE PROPOSED DICTIONARY OF MECHANICAL FALLACIES.

As this has been thought rather anomalous and outré, a few thoughts on it may not be deemed out of place. The proposition is not so preposterous as it may seem, nor is it so at all. The principle is universally recognised. In all things we need to be shown the evil and the good. To appreciate the one we *must* know something of the other. While ignorant of follies, how can we become wise? Intelligence is a ceaseless struggle with error in social, civil, political, philosophical, mechanical, and every other department of life. In none is truth obvious at first; so far from lying on the surface to be stumbled on, it has to be sought for, dug for, and that earnestly and perseveringly. There are what may be called ordinary deductions, extrinsic rather than intrinsic, but truth is the inbeing, the essence of excellence in every thing. In the arts it is the shortest way to an object or end; it goes to it in straight lines, while error stumbles zigzag around it. It is swiftness, strength, elegance, or whatever the attribute may be. In forms and proportions it is beauty; in the absence of meretricious accessories and ornaments, it is taste. The simpler a machine is, the truer it is, for the expression of truth is simplicity. Then mechanical like moral verities only are enduring.

Another point about truth is, that people never speak of it as something to be estimated, as are lands, money, and goods, *by the quantity*. The idea seems to prevail that where it is, error cannot be, that the two can no more mingle than fire and water; whereas, truth is in reality alloyed in every conceivable proportion. Here it is largely manifest; there, like a grain of silver in a pig of lead, its presence is not suspected. It is therefore something of which a little will not suffice in physics any more than in morals. It may exist in a mechanical process or device, and be neutralized by association with fallacies; of which every poor machine is a proof. Results can only improve as it predominates; and herein lies the difference between the works of nature and those of man. In the former all is truth and consequently harmony and beauty, while discords and deformities characterize the latter. The best of these are to be improved by adding to the amount of truth in them.

As a class, to none is the caution, "Beware of Fallacies," more necessary than to inventors. Of all men they ought to know that truth is only to be reached through conflicts with error—through that which steals on them in flattering guise and captivates them with plausible counterfeits. It may seem strange that so many keen and shrewd inquirers fall into mechanical sophistries, and what is worse, fall in love with them, but the illusions are too seductive to be resisted. The fact is as true in physics as in morals,

> "When fiction rises pleasing to the eye,
> Men will believe because they love the lie."

Witness those who yet befool themselves with Perpetual-Motions, the grossest of mechanical falsehoods.

In ordinary as in the highest affairs, directions abound to prevent people from going astray. We have guide-posts for travellers on common roads, and Government spends millions to make seamen acquainted with shoals and other dangers of navigation by day, and on beacons and lighthouses, to direct them into safe harbours at night. For the benefit of merchants there are in most cities, "Commercial Agencies," institutions whose only capital consists of dictionaries of solvent and insolvent traders. And have we not lists revised weekly of counterfeit bank bills, and spurious coin? Naturalists are as earnest in discovering and making known noxious, as innocuous animals and plants, while chemists keep adding to the list of vegetable and mineral poisons. Such are examples of measures adopted to make evils known, that they may be avoided, and which are increased and extended as occasions call for them.

Why then, it may be asked, has nothing been done for those who are devoted to the progress of the arts to warn them of paths that lead them astray? Why should they be left without compass or chart to find their way over the ocean of speculation? Simply because the necessity for such help was not perceived or not sufficiently felt. If not yet palpable, it cannot, we should suppose, be much longer ignored. There is no valid objection to its removal, for whatever may be thought of the exposure of moral offences, the making public transgressions of mechanical laws can do no harm, but much good. A hand-book of errors is a guide book to truths. It would open the eyes and diminish the number of offenders.

As progress depends upon original thinkers, and especially those whose labours comprise the magnificent and minutest exemplifications of applied science, a work calculated to save them from loss of time, and much useless expenditure of thought and labour, must be of permanent and universal interest. But its value would not be confined to them. The reform it would work out in the Patent Office should not be overlooked, in abridging its labours, putting an end in a great measure to inadmissible claims, to disappointments and angry feelings attending rejected applications, to appeals of members of Congress in behalf of their constituents, to contingent fees of agents, and to other improper influences and interferences. Added to which it would raise the value of every legitimate claim, diminish the number of lawsuits, and give to the office an honourable reputation as an Institution of Science. Its reports would cease to record monopolies for ancient contrivances and modern abortions.

The running of anything like a parallel between the laws or principles of ethics and physics may be unusual, but is not improper, since they are intimately and inseparably allied. Emanations of the divine mind, they are equally divine. The same in their origin, essence, and purpose, it is they that impress the Deity on the material and the immaterial; hence the visible creation is an exhaustless exposition of the principles on which the arts must for ever rest; and nothing is more certain, whatever may be the case with transmundane intelligence, than that our species can only advance in civilization and happiness, as it advances in the knowledge and application of them. With us, moral truths begin with, and keep pace with, the physical. As a savage, man has no morals: they are incomprehensible to him. "Even the Arab robs the traveller with as little compunction as a bald eagle wrongs a fish-hawk, while the Feejian eats a missionary as unconscious of guilt as a tiger feasting on an antelope, or a lion making a meal of a Bosjesman." Material are moral forces. The hut and the hearth, the spindle and loom; the plough, forge and lathe; steamships, railroads, telegraphs, and printing presses, are products of mental and contributions to moral power. I mention these things because, to my mind, they are prophetic of the exaltation and influence of mechanical science to a degree that has probably not yet been suspected; and that the higher it rises the closer will be found its affinity with moral science. This *must* be so, since Truth in its infinitely varied forms and relations, like its Author, is ONE.

There are, and perhaps always will be, those who suppose the climax of mundane felicity was reached long ago. Panegyrists of former times, they think the world grows worse as it grows older. Looking back to a legendary age of gold, one of imaginary innocence and happiness, they mourn that it has passed away. An opposite and healthier sentiment now prevails, viz.; that the elements of civilization were never so numerous and so efficiently active; that great as has been the modern increase and diffusion of knowledge, and wonderful the achievements in science and the arts, all are but preliminary to others still greater. This is a corollary of the prime doctrine of progress; that nothing in creation remains stationary or is designed to retrograde. While we realize all that we are prepared for, we transmit it with an increased volume and impetus to our successors, whose mission it will be to forward it, in like manner, to theirs; every age being a debtor to the preceding one, and a creditor to that which follows it. Is it asked, how long can this continue—Can additions to human knowledge be perpetual? Yes: at all events, as long as the forms, motions, and properties of

matter here are not worn out. But may not the intellect become unequal to the successive development of new principles and management of new forces? No: It is indisputable that the more it is expanded, the more readily it apprehends and lays hold of new truths; and it is in a high degree probable that these become more lucid and simple as they become more comprehensive and sublime. —*Journal of the Franklin Institute.*

CORRESPONDENCE.

A HARD CASE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—The case of Mr. Fourdrinier having caused so much discussion at the last meeting of the Electric and International Telegraph Company, respecting the £1,000 being voted on his behalf, I trust you will allow me to bring before you a few remarks upon the partiality thus shown in the distribution of the Company's bounty. I have not the presumption to allude to a case regarding the "first-class" officers, and am aware of the privileges gentlemen holding high positions in a company are entitled to, but the case to which I refer is that of the late Thomas Partridge, of Stoke-upon-Trent, who entered the Electric Telegraph Company at its first organization, eighteen years ago, and remained with it till the day of his illness, without ever having a blemish on his character. He was in the discharge of his duties in Harecastle Tunnel, testing the telegraph company's wires, when he was afflicted with a paralytic stroke. This occurred about 2.30 p.m. He was taken home by the train, and lay insensible for two months. When the poor man's money was paid, it was found (to the surprise of his wife) that the fourth part of a day's pay was stopped, which was the large sum of 11*d*. He lay for upwards of two years in a state of imperious want. On the suggestion of one of his fellow-workmen, application was made to the superintendent at Manchester, to allow a subscription to be opened on the line for his behalf. This was refused. After continued intercessions by the inspector at Stoke, he obtained the small grant of *£5*; after the man had spent the best of his days in the service of the Company, attending scrupulously to his duties. It certainly establishes a striking contrast between the head officers and the working man; as the one receiving a handsome stipend, and sheltered in a comfortable office from any bodily danger, has, apparently, a claim to entire sympathy, whilst the other, working hard for years in conditions often prejudicial to his health, or dangerous to his life, is scantily recompensed with the four hundredth part of what is now allotted to the ex-secretary. Of course the old adage will always be good :—" L'eau va toujours à la riviere."

Yours truly, OBSERVER.

RAILWAY TELEGRAPHS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I read with much interest the leading article in your last number entitled the "Egham Accident," in which you notice my train signalling telegraphs, pointing out some of their defects as well as some of their good points, and, as the question of signalling trains by telegraph is at present engaging the attention of railway managers, I shall feel obliged if you will permit me to offer a few remarks with a view to correct two or three errors that have been made in describing my instruments, feeling assured that your only object in permitting the article to appear in your useful journal was with the view of bringing the important subject of train signalling fairly under the more immediate notice of the railway world.

It is stated as a "defect" that my instrument "is worked by *one* line, and is actuated by *momentary* currents." Now this is not necessarily the case, for they can be readily adjusted and connected, so as to work with one, two, or more wires, and also with permanent currents should it be so desired; but as after several years' practical experience I find that one wire is the most efficient, and further, as in my opinion the employment of two or more wires with permanent currents constitutes an element of danger, I do not recommend their employment, except in certain very special cases where the peculiar nature of the traffic requires some special adaptation. In connecting up my instruments the battery circuit is not persistent, and does not, therefore, continually get weaker and weaker until failure of signals takes place, but is only called into action at the moment of transmitting a signal, and in the event of the line-wire being fractured, there is no possibility of the broken wire fouling either of the others (as is the case when two or three wires are employed), or of its permanent current dividing and entering one of them, thus recording a false signal at the distant station.

The indicators are not magnets, and therefore cannot be demagnetized, or their polarity reversed by lightning—a frequent cause of trouble and annoyance in needle instruments, and in some cases a frightful source of danger, by making one needle at a station show "line clear," whilst at the next station it shows "line blocked."

Again, "two opposite trains cannot be signalled at the same time." This is an error; two opposite trains can be signalled at the same time; but I would observe that such an act being contrary to instructions would subject the signalman to immediate suspension; the rule being that no one signal is to be considered complete until the reply has been received and acknowledged.

Again, "the wrong button may be pressed where the same signal has to be given at one time on one button, and at another time on a different button." I cannot understand how there is any "defect," the signalman in charge having constantly before his eyes a permanent indicator, showing *which* button is to be pressed, and has not to trust to memory. In some cases I employ a separate ringing key with *one* button, and as all call signals are made with this no mistake can occur.

In the construction of my instruments I have endeavoured to meet the requirements of every description of traffic, and, in order to suit the wishes of general managers and superintendents, have arranged the mechanical details in such manner that, in lieu of employing indicators, the dials can be fitted with miniature signals in exact accordance with the out-door signals employed on any particular railway—viz., semaphores, revolving discs, cross-arms, &c.

In conclusion, permit me to thank you for the flattering remark that "my instrument possesses many admirable points, and is extensively employed." I naturally infer that the latter result has been obtained in consideration of their "many admirable points," for although during the past twelve years I have had to contend against considerable opposition from several rivals, yet I am glad to say my instruments continue to make their way, and to give general satisfaction wherever they have been adopted.—Your obedient servant, EDWARD TYER.

15, Old Jewry Chambers, E.C., Sept. 7, 1864.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In your article upon the "Egham Accident" I read a passage which—unless I misunderstand it—does not accord with my experience of the needle block system. In the passage to which I refer you say "They are the needle (Clark's, Spagnoletti's, &c.) and Preece's system as employed on the South-Western Railway; but the latter is immeasurably superior to the former, inasmuch as the man at one station has no control over the signals at his own station, and is fully and firmly assured by repeating signals that every signal sent is not only properly received, but duly acted upon."

Upon the London, Chatham, and Dover line of railway the telegraph block system is carried out to its fullest extent, and on the company's Metropolitan Extension the single needle block instrument, as modified by Mr. Rudall, has been used for the last two years with entire success. The dial of the instrument has on one side the words "line blocked" painted in bold capitals; on the other side are the words "line clear." A hole passing through the visible part of the axle of the reverser is fitted by a moveable pin, which, when in use, pegs the needle over to "line blocked." When it is necessary to send a train, say, from Herne-hill to Dulwich, the signalman at Herne-hill calls Dulwich by repeating three strokes of the needle to "line blocked." The man at Dulwich acknowledges this signal by repeating back three strokes of the needle, and then pegs his needle over to "line blocked," as permission for the train to come on. As soon as the train has cleared his station the man at Dulwich gives Herne-hill three strokes to "line clear." This signal is acknowledged, and the needles are left perpendicular until it is necessary to send on another train.

Now, Sir, the needle being pegged over by the man at Dulwich, Herne-hill has no control over it, and cannot use his instrument until Dulwich has unpegged and given "line clear." Is not that what is meant by "the man at one station has no control over the signals at his own station?" Again, every signal is acknowledged by repeating back the same number of strokes as given, and in the case of a "train out" signal, the needle is at once pegged over by the man who receives the signal. Is not the man who receives the acknowledgment "firmly and fully assured that every signal is not only properly received, but duly acted upon?" In addition to this, no train is allowed to leave one station until the signalman in advance has acknowledged the "train out" signal, and pegged his needle over; and in the event of the telegraph being broken down, or unintelligible signals being received on the instruments, every train is stopped, and the engine-driver and guards verbally cautioned to proceed slowly to the next station.

From the above I think it will be acknowledged that for every practical purpose the needle block, as used on this line, is a thoroughly efficient system. The only fault that can be alleged against it is the liability of the instruments to demagnetization and reversal. Should the first occur the telegraph would appear broken down, and should the needles become reversed unintelligible signals would be received. In either case the signalman would bring approaching trains to a standstill, and verbally caution the engine-drivers and guards.

I must apologise, Sir, for troubling you with this letter, but I am aware that your only object is to ascertain and make known the exact truth respecting all telegraphic matters, and therefore I am sure you will be glad to do justice to all parties by allowing each system its fair share of credit. I do not wish to question the advantages of Mr. Preece's instrument, but as it appeared to me that it was being specially praised for doing the same thing as our needle block, and I knew you had not personally examined our system, I thought you would pardon me for pointing out what appeared to be a discrepancy between your article and my experience.—I am, Sir, your obedient servant, W. H. FLOYD,

Assistant Telegraph Superintendent.

Telegraph Depôt, London, Chatham, and Dover Railway, Sept. 7.

AGGRAVATING FINES IN TELEGRAPH OFFICES.

To the Editor of the Telegraphic Journal.

Sir,—If through the medium of your paper you will allow me to call the attention of the executive committees of the several telegraph companies to the injustice consequent upon the irregularities in the existing system of "fining" for mistakes which may occur in the transmission of messages, you will confer a boon on telegraphists in general. What with contacts, failure of signals, disconnections, &c., it seems a great hardship to be fined at all, except in such cases where the error arises from sheer carelessness; but if the directory consider that this mode of punishment is indispensable, then, at least, let them see that it is administered as fairly as possible. It would appear that at present fines are inflicted according to the apparent magnitude of the error "upon paper," whereas they should be adjusted according to their actual magnitude when "practically analysed."

Again, the sender, receiver, and writer of a message is subjected to pay for an error which, by an experienced hand, can be easily traced to the sender, receiver, or writer individually, as the case may be. There is a kind of an appeal against these fines acknowledged, but as they (the fines) are always "paid under protest," and nothing is ever heard of the appeals, I presume that, protest or no protest, the result is equally lamentable. These irregularities could be remedied by the appointment of supervisors practically acquainted with the working of the different codes, who would be able to judge of the magnitude of the mistakes, and by whom committed. I believe that in the Electric Company the money produced by fines is contributed to the maintenance of a "clerks' library," and need scarcely add that the Magnetic Telegraph employés would be very thankful if such a privilege be extended to them. Trusting that I shall not intrude too much upon your space,—I am, Sir, your obedient servant, A Victim.

COVERING COPPER WIRE, &c.

To the Editor of the Telegraphic Journal.

Sir,—Would you or any of your readers kindly give me a description of a simple machine for covering copper wire with silk or cotton, for making induction coils, or, if that would take too much space in your valuable journal, would you kindly refer me to any book, or paper, that contains a description or drawings of the same? Would you also kindly state what is meant by *resistance coils*, and how made, and what they are used for? An early reply to the above will greatly oblige, Volta.

[Our correspondent will find the information as to the resistance coils, and their application, in the appended extract from a valuable paper by Mr. W. H. Preece, on the testing of submarine cables:—"The basis of all resistance tests is the fundamental law of Ohm, which is expressed by the formula:—

$$R=\frac{L\,C}{S},$$

where R=the resistance;
L=the length of the wire;
C=the specific resistance of the material employed;
S=its sectional area.

The specific resistance of different metallic bodies (C), varies considerably, as will be seen from the following relative conducting powers of different metals, according to Becquerel:—

Copper	100	Platinum	16·4
Gold	93·6	Iron	15·5
Silver	73·6	Mercury	3·45
Zinc	28·5		

The relative conducting powers of iron and copper, which are the materials usually employed for telegraphic purposes, are, consequently, as 15·5 to 100, or as 1 to 6·45 nearly. The resistance of a wire is directly as its length (L), and inversely as its sectional area (S.) If A B represents a copper wire 1 mile in length, and C D one 10 miles in length, both being of the same dimensions and material, the resistance of C D will be exactly ten times that of A B; but if the sectional area of A B is reduced to one-tenth, then the resistance of A B will be exactly equal that of C D. Again, if the wire A B is made of iron instead of copper, the same dimensions being retained, the resistance of A B will be six and a-half times greater than that of C D. If now, A B is reduced to six and a-half times its length, its resistance will again equal that of C D. Thus a short length of fine iron wire, will offer the same resistance to the passage of an electric current as a long length of ordinary-sized copper wire, and will produce the same phenomenon. One mile of No. 40 iron wire offers the same resistance as about 500 miles of No. 16 copper wire. Short lengths of this iron wire are cut to represent any separate lengths of copper wire of the usual dimensions, and are wound round bobbins, forming a series of what are called "resistance coils." They can be made to represent any length of cable, but the series usually constructed consist of 221 miles of No. 16 copper wire. By these means, the resistance of any cable can be ascertained, it being only necessary to compare the resistance of the material of which it is made with that of No. 16 copper wire. Thus the resistance of the Channel Islands cable is to that of No. 16 copper wire as 36 to 17; consequently, 17 miles on the author's resistance coils are equal to 36 miles of the Channel Islands cable. In the case of the Gibraltar cable 1 mile on these coils would represent 8 miles of that cable."—Ed. T. J.]

TELEGRAPHIC NEWS.

The Telegraph in Russia.—*Le Moniteur*, in a despatch, dated Trebizonde, 19th May, announces that telegraphic communication has been established between Constantinople and Trebizonde.

The Telegraph at Buenos Ayres.—By the last mail we have the following information to the 27th July:—"Congress is still sitting. A bill granting a concession for the construction of a telegraph line between the city of Buenos Ayres and Monte Video has been passed."

The Persian Gulf Telegraph Cable.—Owing to a break in the submarine telegraph cable of the Persian Gulf line, it has been announced that no more messages will be sent by that line beyond Gwadur, until further notice. The Amberwitch has been dispatched from Bombay, to pick up the cable and repair it.—*Times of India.*

Colonial Telegraphy.—The telegraphic extension from Deniliquin to Hay (New South Wales), a length of eighty miles, was opened for messages on the 9th of June, having previously been inspected by the superintendent of telegraphs. Progress is being made with the extension from Wellington to Dubbo, and also with that from Braidwood to Queenbeyan; the latter line will soon be finished. The tender of Mr. D. Macquarie had been accepted for the extensions from Mudgee to Murrurundi, at a cost of £37 per mile.

Telegraphing without Wires.—Experiments are now in progress, both at Mount Valerien and Vincennes, for the purpose of testing a new system of electric telegraphy invented by M. Armand Douat, who, it is said, has found means to do away, as Mr. Haworth has already done in England, as stated in his specification, with conducting wires altogether, and transmit despatches by the sole action of the earth. A zinc and a copper-plate, bent in spindle-like shape, are buried in the ground, with their convexity turned in the direction in which the despatch is to be sent.

The late "Eisteddfod" at Llandudno.—We quote the following from the *Carnarvon and Denbigh Herald*, of the 3rd inst.:—"The want of a telegraph station, much as its absence has been complained of, was never so much felt as during last week, when, to ensure the transmission of a message, it was absolutely necessary for the sender to go down to the junction with it, and see it safely on the wires. Will it be credited that, in these days of modern improvements, a town with a resident population of more than 3,000, and a summer population of more than treble that number, having a railway station itself, and being within four miles of another on the principal line in the kingdom, can still be without a telegraph station. Yet that such is the case we ourselves had only too certain a proof on Friday last, when a message, sent by us from Carnarvon, to our reporter at Llandudno, was *only* four hours, from the time it reached the junction, until it was delivered to the "chiel," who was then sleeping the sleep of the just. This is not a singular instance by any means; a gentlemen complained, but a few days previously that a message sent to him was delayed over three hours at the Llandudno station."

Telegraphic Aid to Commerce in Jerusalem.—"Jerusalem," says the British consul in his year's report to the Foreign Office, "is the least commercial or industrial city I know." British trade is represented by one English tradesman, who keeps a store for English upholstery, drapery, and fancy goods. The population of the city is computed at 15,000, rather more than half of them Jews, the rest Moslems and Christians. The chief native industry is the manufacture of soap and "Jerusalem ware," this latter consisting of chaplets, crucifixes, beads, crosses, and the like, made for the most part at Bethlehem, and sold to the pilgrims, who annually flock to the holy city to the number of about 6,000. The population of the entire Sandjak, or province, is estimated at 200,000, of whom 160,000 are Mahometans. Owing to the absence of good roads and the insecurity arising from the predatory tribes of Bedouins inhabiting the outskirts of the district, but who could easily be kept in check, vast and fertile plains lie waste or are but partially and poorly cultivated; factories are not to be met with, and no mines are worked, though it is believed that sulphur, bitumen, and rock salt abound on the shores of the Dead Sea. The principal, if not the only imports from England are cotton goods, and some colonials, but the former have much diminished since the cotton crisis; it is calculated that 300 bales of these goods, of the value of £16,000, annually find their way here. The exports are olive oil and grain. Very little is done in cotton culture, what is raised being of inferior quality and consumed on the spot; but it is believed that in many parts of the country cotton to a large extent might be successfully cultivated, with good seed and proper instruction and implements given to the peasantry. The vegetable produce is barely sufficient for local requirements. Jaffa is the port through which Jerusalem deals with foreign countries. The trade of Jaffa experienced a considerable increase in 1863; the quantity of cotton exported rose from 55,000 lbs., in 1862, to nearly ten times the amount in 1863, with a prospect of this being again trebled or quadrupled in 1864. This was owing to the interest exercised. The merchants who operated in cotton made a profit of 25 per cent. There are regular lines of French, Austrian, and Russian steamers, all doing well, and very often large quantities of goods have to be left behind for want of room; but only one English steamer visited Jaffa in 1863. The exports exceeded £200,000; of the imports no statistics are kept. The consul reports a telegraphic line in course of formation by the Government between Beyrout and Jaffa, thence to be carried on to Alexandria.

TELEGRAPHIC BRIBERY.—Two wealthy merchants of Ahmedabad have been sentenced to three months' imprisonment for bribing an electric telegraph signaller.

TELEGRAPHIC COMMUNICATION BETWEEN CAIRO AND CONSTANTINOPLE.—In the course of a few days (says the *Levant Herald*) Constantinople and Cairo will be in telegraphic communication. The electric current, flashing over a distance of 1,800 miles, will connect the capital of Turkey with the chief city of its great Egyptian dependency. The Turkish authorities have already finished their part of the undertaking. On the 12th ult. the telegraphic line was completed as far as El Arish, on the Turco-Egyptian frontier, and it is understood that, in two or three days, the Egyptian engineers will link their portion of the line to that of their Ottoman *confrères*, and so complete the whole. There will be a double line of wires throughout the distance, one for messages in Turkish and Arabic, and the other for messages in French and other European languages. A convention is on the point of being concluded between the Turkish and Egyptian telegraphic administrations, by which the tariff of rates for the dispatch of messages will be fixed, and thus, within a week hence, the public in Constantinople will be in a position to communicate by telegraph direct with Cairo, or with any of the intermediate stations on the line. The commercial and general advantages which the completion of this line offers are too manifest to need comment.

EUROPEAN TELEGRAPHS.—The telegraphic lines in France, exclusive of those used by railways, comprise 96,446 kilometres (each three-quarters of a mile) of wire, and 1,301 offices, which yearly transmit about a million and a-half of private despatches, and nearly as many official ones. Russia has 48,840 kilometres of wire; Austria, 29,640; Italy, 25,561; Prussia, 32,223; Spain, 23,665; Belgium, 6,236; Switzerland, 4,960. In none of these countries is the telegraphic administration connected with the post-office. In Spain, as in France, the telegraphs are under the control of the Minister of the Interior. In Russia, Prussia, and in Italy, they belong to the Ministry of Public Works. In Belgium, the telegraph, railways, and the post-office, form a general direction under the Minister of Public Works, but are kept distinct. In Austria, the administrations of the telegraphs and the post-office were at one time united, but it was found expedient to separate them. In Switzerland the telegraphic organisation is nearly the same as Prussia; the post-office, customs, and private establishments supply the elements of an auxiliary staff, but all the persons employed depend on the Administration of Telegraphs, and are paid, after the budget, for whatever concerns the service. There is, therefore, no foundation whatever for the assertion made by the committee on the budget, to the effect that the practice of several neighbouring countries demonstrated that the union of the post-office and the telegraph service presented an impossibility. Such practice exists elsewhere.

MISCELLANEA.

A "JAW-BREAKER."—As an instance of the abominable system of terminology at present adopted by chemists, it may be mentioned that Mr. M. H. Schiff, in a monograph on some derivatives of ethylidine, states that he has succeeded in obtaining a chloride of *dimercurodiethylidinediphen-ammonium*. If any one out of the laboratory can pronounce this awful term, we shall be very much surprised.

MAKE HASTE SLOWLY.—There is an old Latin proverb (*Festina lente*) which says, "hasten slowly." It is rarely that we find two words which express so much or contain more food for thought. As a nation we make haste too fast, and should do better to go much slower and more surely to our goal. Some individuals manifest this disposition to hurry over important things differently from others, but the application of the fault alluded to may be understood by the following illustration:—Suppose a person to require information upon some subject he is comparatively ignorant of—the steam engine indicator, for instance; having procured a book upon it, he runs his eye over page after page, touching first upon this example, now upon that, until he arrives at the end, when he knows nothing whatever of the subject. The first time he undertakes to converse upon the instrument or to apply its principles practically, he discovers his ignorance, and is put to shame or inconvenience. All this is wholly the fault of making haste to reach the end, without grasping the fundamental principle and mastering it, and each detail also, before going further. It is absurd to suppose that any matter worthy of study can be mastered in a cursory examination, yet very many persons relinquish the pursuit of knowledge in despair from this very cause. Finding it impossible to comprehend in fifteen minutes some point it has taken an author as many days, and weeks, probably, to settle, they deem the matter beyond their comprehension, and throw up the study never to return to it. There may be some gifted spirits to whom the knotty points of a new theory, or the intricacies of an unfamiliar science are clear and plain at first sight, but the mass acquire knowledge only by patient study, not by a hand-gallop through the fields of learning. When sensible men go abroad to acquire information in foreign countries they do not take express trains and steamboats, and whirl onward to the end; but, staff in hand, they penetrate into village and hamlet, and learn from the peasant and the prince. So it is with those who study to learn, and retain what they read. Patient plodding by the wayside is better than running from pillar to post, and the truth of this assertion is manifest to all who have ever given the subject attention.

INTELLIGENCE AND WEALTH.—Now, it is obvious that there is nothing in the profession of abstract science, let it be ever so successfully practised, which will certainly lead to the acquisition of wealth; and by wealth I mean what a successful London banker, merchant, or lawyer would term wealth. It is the practical men who generally contrive to run off with the sugar plums of science; and there is no reason why they should not. What these men do is palpable and manifest to the public, but not so the work of the philosopher, to which they are most deeply indebted. Every one wonders at and admires the electric telegraph, but how few think of the philosopher who discovered the law upon which the whole system depends? Just so is it with the art of electro-plating. The names of electro-platers may be known to the world, but how little those of the men who laid the foundation of the science of that valuable art! The magneto-electric machine, now so usefully applied, was the result of a discovery by Mr. Faraday, which, although it did not confer wealth on its author, yet has made others rich. I might go on multiplying examples until I should fill all the columns of the *Telegraphic Journal*, but those above-mentioned shall suffice. The conclusion which I would draw is, that, there may be intelligence which is worth something, though it make not wealth for itself.

THE MYSTERIES OF IRON.—There is no miracle recorded in the annals of any religion more mysterious, more incomprehensible, more inconceivable, than some of the well-known properties of the simple metal, iron. Consider, for instance, its change from its ordinary to its passive state. If a piece of the metal in its ordinary condition is immersed in nitric acid, it is powerfully acted upon, entering into combination with the acid and losing its metallic form; but if a piece of platinum wire has one end inserted in the acid, and the iron is then immersed in contact with the wire, it is so changed that the acid has no power upon it, and this condition continues after the platinum wire is withdrawn. The contact of a single point with the platinum sends a transformation through all of its particles which renders them invulnerable to the attacks of the most powerful acid. Even more wonderful is its change under the influence of a current of electricity. When a bar of pure soft iron is wound with an insulated wire, and a current of electricity is sent through the wire, the bar is instantly converted into a magnet; it is endowed with an unseen force which stretches out from its ends, and seizing any other piece of iron within its reach, draws them to itself, and holds them in its invisible grasp. The object of insulating the wire is to prevent the electricity from leaving it, and yet through this insulating coat a power is exerted which changes so strangely the nature of the iron, enabling it to act on substances with which it is not in contact. As soon as the circling current ceases, the iron becomes like Sampson shorn of his locks, its miraculous power has departed. Not less mysterious than either of these is the more familiar phenomenon of the fall of a piece of iron to the ground, under the simple action of gravitation. What is that invisible force which reaches out in all directions from the earth, and clutches all matter in its grasp? The fibres of this power are imperceptible to any of our senses. If we pass our hands under a suspended rock we can feel nothing reaching from it to the earth; and yet there is something stretching up from the earth, taking hold of the rock, and drawing it down with the strength of a hundred cables! We walk enveloped in mysteries, and "our daily life is a miracle."—*Scientific American*.

INDIA-RUBBER MANUFACTURE.—India-rubber, under the hands of inventive men, has become one of the most widely and diversifiedly-applied substances in the modern arts. Not many years ago it was simply known as an elastic resin (misnamed "gum") termed caoutchouc, which was made into certain articles that were impervious to air and water; but it became sticky and soft at a low heat, and was therefore unfit for common purposes. In a pure state it is still incapable of being very usefully applied, but by combining it with other substances, especially sulphur in small proportions, and submitting it to heat—the process called "vulcanisation"—it is made to retain its elasticity, and at the same time resist the action of heat to soften it at temperatures below that of common steam-heat. Waterproof overcoats, blankets, shoes, toys, and numerous other articles are manufactured out of elastic vulcanised rubber, while pencil and pen-cases, combs, rollers, flutes, canes, &c., are made of hard vulcanised rubber. The manufacture of toys, belting, and water-hose is carried on upon a large scale by the New York Rubber Company, in their factory at Wiccapee, situated in a romantic dell on Fish Creek, near the Hudson river, in Dutchess county. We lately enjoyed the pleasure of visiting this factory, and witnessed the various operations of grinding, mixing, calendering, moulding, vulcanising, and finishing the various products. The rubber is first ground, or rather kneaded between large iron rollers, and during this operation it is mixed with other substances, such as white lead, &c. It is here reduced to sheets, resembling bakers' dough, which are afterwards submitted to a "calendering" action—that is, they are pressed between large, heavy, polished iron rollers. Several machines having three rollers, placed one above another, are used; and one has four rollers, between which the mixed rubber is passed three times, and reduced to beautiful, smooth, and thin sheets. From such sheets the several parts of hollow dolls, balls, globes, &c., are stamped in dies, then the parts are united with rubber cement, trimmed, and fitted into metallic flasks of different patterns, then placed in batches in a large horizontal iron oven, where they are submitted to the action of steam of about 240° Fah. for five and a-half hours. The articles are secured upon a carriage, and moved upon a railway into the oven, one end of which opens and closes, forming a large man-hole. After the goods are vulcanised they are finished and

painted. Hundreds of designs and moulds for different articles are used in this manufactory, and artists are constantly employed in getting up new designs and making new moulds. The high price of leather has caused much attention to be devoted to the manufacture of some suitable substitute for it in large beltings, and success has been attained with india-rubber combined with strong flax-duck, made for the purpose. The fabric is woven in looms, and several plies of it, stitched together by machines, are cemented with india-rubber, and then cured by solar action. We were told in the factory that india-rubber belting, cured by vulcanisation, is not so durable, owing to the strength of the flax-cloth body being impaired by the high steam-heat. We examined one belt, 3 feet in width and 252 feet in length, which weighed about 1,600 lbs., and cost from $1,800 to $1,900. It was made for the driving-belt of an elevator at St. Louis, and another of the same size, for a similar purpose, has been ordered for the Milwaukee and St. Paul Railway. This belting is composed of five plies of stout flax-duck, and it has twenty-seven rows of stitching in it. A very large business in manufacturing such belting is now carried on at this place. Orders for nine belts, each 22 inches wide and 269 feet in length, are now being fulfilled. India-rubber hose are made of strong flax-duck, which is woven here in tube form, in looms adapted for the purpose. After coming from the loom the flax-duck hose, of a certain length, is laid upon a long table, and wrapped around on the outside with a layer of india-rubber in a sheet. This is cemented to the duck, and is to form the inside of the hose. A long iron rod is now thrust through the inside of the hose, and hooked at the back end. The hose is now drawn over this rod by a reel, and turned inside out like a stocking, after which another layer of sheet rubber is laid and cemented upon the outside, thus forming a perfectly close hose, water-tight inside and out, without a rivet from end to end. Of course, such hose is far stronger than that made of leather. It must be gratifying to machinists, millwrights, and engineers to know that such heavy and strong belting is now manufactured, and that it is capable of withstanding the action of the weather in a very superior degree to leather. So far as we can recollect we have never seen leather belting of such dimensions made or used anywhere. —*American Artizan.*

Telegraphing without Wires.—In order to account for a class of spirit manifestations, writers assume that two human brains, placed at a great distance from each other, may become filmily meshed together by odylic threads, so as to form a double cerebral unit; the impressions of the stronger brain being communicated to and through the weaker. Thus, a brain situated in England can be placed *en rapport* with a brain in Australia, and can telegraph impressions across the globe, imparting information to and through the medium, which neither the medium nor any one in the circle could otherwise have any knowledge of. In this way events occurring in distant places may be accurately described, and sentences be spelled out, partly by the automatic action of the brain of the medium, and partly by the automatic agency of some co-efficient brain in a distant place. The hypothesis can be extended to past events by supposing them to have left a permanent impression on the all-pervading odylic medium. By this theory, all communications received through writing, tipping, rapping, and speaking mediums are accounted for.

The Chemistry of Earth and Air.—M. Bousingault, in writing upon the subject of the nitric formations of Tacunga, explains how easily nitrate of potash is developed in the atmosphere:—Nitre is almost universally distributed, and is very rapidly formed. It results from the oxidation of the nitrogen which is contained in the atmosphere, and its combination with the potass of the soil. Schœnbein has shown that even where no potass exists, there is ammonia formed by combination of the nitrogen and hydrogen of the atmosphere, and this then unites with the nitric acid, forming nitrate of ammonia. These combinations are not deemed worthy of consideration by British agriculturists, who apply ammonia to their soils artificially. In Saxony a very different state of things exists, for there Baron Liebig's views are carried out to the letter.

Why Bees Work in the Dark.—A lifetime might be spent in investigating the mysteries hidden in a bee-hive, and still half of the secrets would be undiscovered. The formation of the cell has long been a celebrated problem for the mathematician, whilst the changes which the honey undergoes offer at least an equal interest to the chemist. Every one knows what honey fresh from the comb is like. It is a clear yellow syrup, without a trace of solid sugar in it. Upon straining, however, it gradually assumes a crystalline appearance—it *candies*, as the saying is—and ultimately becomes a solid mass of sugar. It has not been suspected that this change was a photographic action. That the same agent which alters the molecular arrangement of the iodide of silver on the excited collodion plate, and determines the formations of camphor and iodine crystals in a bottle, causes the syrupy honey to assume a crystalline form. This, however, is the case. M. Scheibler has enclosed honey in stoppered flasks, some of which he has kept in perfect darkness, whilst others have been exposed to the light. The invariable result has been that the sunned portion rapidly crystallizes, while that kept in the dark has remained perfectly liquid. We now see why bees are so careful to work in perfect darkness, and why they are so careful to obscure the glass windows which are sometimes placed in their hives. The existence of their young depends on the liquidity of the saccharine food presented to them, and if light were allowed access to this the syrup would gradually acquire a more or less solid consistency; it would seal up the cells, and in all probability prove fatal to the inmates of the hives.—*Quarterly Journal of Science.*

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2123. R. A. Brooman, improvements in signalling apparatus, especially applicable to signalling on board ship.—A communication.

2134. G. Wilton, improved means of communicating between passengers, and between passengers and guards, on railways.

2141. Sir J. Mackneil, improvements in railway signals.

2147. J. H. Johnson, improvements in apparatus for sounding alarm or signal bells.—A communication.

2151. J. S. Guy, improvements in apparatus for enabling passengers travelling by railway trains to communicate with the guard and driver.

2158. A. M. J. Count de Molin, an improved electro-magnetic engine.

2165. J. Barber, improvements in communicating, watching, and signalling throughout railway trains.

GRANT OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1840. T. P. E. Le Boulenge, an electro-balistic chronographe.

PATENT SEALED.

562. C. Humfrey, improvements in vulcanizing india-rubber.

PATENT WHICH HAS BECOME VOID.

2249. J. Ronald, improvements in laying or depositing submarine telegraph cables.

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

2185.—W. Clark, improvements in signal apparatus applicable for the prevention of railway-train collisions.—A communication.—2nd September, 1861.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

D. E. H.—Your observations with respect to the telegraph company in question are perfectly correct. We desire to act in a fair and impartial manner towards all the companies in recording their proceedings. We thank you for your promised assistance, and shall be very glad to avail ourselves of the same at all times.

A Nautical Man.—A system of electric ship-steering signals has been patented by Lieutenant A. Gilmore, R.N., and Mr. W. H. Preece, C.E., which has been approved and adopted by the Lords Commissioners of the Admiralty.

As information respecting Improvements, Extension of Lines, and Progress of New Undertakings will at all times be most acceptable, we hope that our readers will kindly render us assistance, by furnishing us with brief notices of events and occurrences in connection with electrical and scientific progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

THE SUCCESS OF TELEGRAPH COMPANIES.

The tendency of the present generation to speculate, and the passing of the Joint Stock Companies' and Limited Liability Acts, have given opportunity to adventurers to impose upon the public; but of the 2,000 projects recently introduced into the money market we have failed to recognise a telegraphic undertaking which has not a legitimate claim to support. We have of late years fallen into a grievous error in estimating the character of men and institutions by the amount of cash at their bankers. If we wish to ascertain the status of any useful Company we generally refer to the columns of the *Times* for information as to the price of its shares, and on the returns of the "leading journal" we base our conclusions. But in this we may err. Notwithstanding that telegraph shares are at a discount, and offer but little inducement to investors, the various undertakings pay exceedingly good dividends, as will be seen on reference to official documents. On a previous occasion we directed attention to the continued success of the Electric and International and the Magnetic Telegraph Companies. We now take the opportunity of noticing briefly the reports of the Submarine and the Universal Private Telegraph Companies.

The Danish war materially affected the operations of the Submarine Telegraph Company, as, owing to the difficulties in Schleswig and Holstein, their cables were not allowed to be used. It should be mentioned, however, that although telegraphic communication was suspended, the line was treated with the utmost respect by the belligerents, and remained intact to the conclusion of the war. Accordingly the revenue from this source was considerably reduced. The receipts of the Company for the past half-year were mainly earned on the French and Belgium lines. A very large increase in the number of messages transmitted by these lines is shown in the accounts, which are of a very gratifying character. A progressive business has been done (notwithstanding the drawback to which we have adverted), every provision has been made to meet the probable extension of traffic on the continental lines, and a dividend at the rate of 5 per cent. per annum has been declared on the capital—an issue to the half-year's proceedings which is as satisfactory to the chroniclers of telegraphic progress as to the holders of shares in the undertaking.

The Universal Private Telegraph Company is in a very promising condition. At the recent extraordinary general meeting a dividend of 6 per cent. per annum was resolved upon, and hopes were expressed that still larger returns upon capital would be realized. The Act of Parliament under which the above Company was established only requires that one meeting of the shareholders shall be held annually; but the Directors on reviewing their accounts for the half-year ending 30th June, were so satisfied of the eminently remunerative character of the business, that they determined to summon a special meeting whereat they could recommend an interim dividend. The important position which this Company has attained is to be attributed mainly to the indefatigable exertions of the officers. A question—and a very proper question, considering the recommendation of a dividend of 6 per cent.—arose as to the honorarium of the Directors, who had to the date of the last meeting served the Company without fee or reward. During the period of development of any enterprise it is necessary for the Directors to devote themselves assiduously to their duties, and to wait for an acknowledgment of their labour until such time as the project arrives at maturity. When a Company attains to the condition of paying a handsome dividend to the shareholders, the latter should be liberal in their award to their Directors. In the case under consideration it is evident that all the officers of the Company united to bring about so satisfactory a result as appeared in the statement presented at the last meeting. The shareholders would seem to be aware of the services rendered by the Board of Directors, and unanimously resolved to award them the sum of £600 per annum, and their travelling expenses.

From the foregoing it will be observed that telegraph property is increasing in value, and that it requires no prophetic faculty to enable any one to perceive that in the course of a few years the remunerative character of telegraphs will be established. In bringing these remarks to a conclusion, we must congratulate the officers of both the Submarine and Universal Private Telegraph Companies on the status which their several undertakings have attained, and express a hope that the future to them may be more prosperous than the past.

TELEGRAPHIC CORRESPONDENCE BETWEEN MALTA AND THE CONTINENT.

It is with regret that we have to announce the probability of suspension of a very important telegraph service. No greater calamity could befall a civilized nation than to be deprived of either its literature, its railways, or its telegraphs. Yet one of our most flourishing dependencies appears likely to be called upon to sacrifice its means of telegraphic communication. The spirited gentleman who undertook to do for Malta what Mr. Julius Reuter has done, and is doing, for England and other European nations, alleges that "it doesn't pay," and has intimated that, unless the enterprise receives increased support, either the number of telegrams must be reduced or the correspondence must be discontinued. The *Malta Observer* thus adverts to the inconvenience which would result from the cessation of operations on Stefani's line of telegraph:—

"Our readers will remember that in May, 1863, a proposal was started having for its object the establishment of telegraphic correspondence between Malta and Turin, in order that the public of Malta should be made aware of any political events of great importance passing abroad. This useful proposal received the support of about fifty subscribers during a year, enabling Stefani—the *Reuter* of Italy—to forward twenty-six telegraphic messages per quarter—that is, two telegrams a week—for the sum of £21 a quarter. The total annual subscriptions amounted to about £100, so that there remained £16 to pay for a year's printing and distribution of the telegraphic bulletin. Every honest and intelligent person will admit that the *service* cannot be executed better than through Stefani of Turin, as his agency is the only one at present existing in Italy, and his terms are very moderate. However, this year, instead of an increase in the number of subscribers, thirteen have dropped their subscriptions, and only four have come forward to support the proposal. Six subscribers have left the island, and have also discontinued their subscriptions. We will not stop to inquire into the *causes* that may have induced some of the subscribers to withdraw their support from a useful and harmless undertaking; but we publish a list of the present subscribers, and a list of those who have discontinued their subscriptions. It will be seen that, unless the enterprise receives support and encouragement from respectable English residents and Maltese merchants, either the number of telegrams must be reduced or the correspondence must be dropped entirely. We leave the matter in the hands of the public of Malta, hoping that some proof of public spirit will not be found wanting, and that it shall not be said abroad

that no commercial life nor public spirit exists in Malta. It is true that thousands of persons read the telegrams at the Exchange, in the clubs, libraries, and cafés, and that these public establishments ought to subscribe for several copies of the telegram, in order to encourage a *requirement*, particularly when neighbouring cities are in possession of daily telegrams, and Malta is as rich as any of them. For our parts we shall support the correspondence for a time even at a loss, trusting that on reflection, and in brighter moments, those subscribers who have withdrawn their *patronage* will feel pleasure and honour in supporting so good and useful an undertaking. If it fails, the public will know to whom the failure is to be attributed.

"The following is a list of the present subscribers to the telegraphic bulletin:—

"The Chief Secretary to Government; Major W. Brett; Casino Maltese; Hon. E. Scicluna; Messrs. Rose & Co.; Peninsular & Oriental Company; Mediterranean Extension Telegraph-office; Chevalier R. Slythe; Messrs. James Bell & Co.; Mr. W. Winthrop; La Borsa; Mr. John Rose; Marquis Drago; Mr. G. Grant; Sir A. Dingli, C.B.; Mr. George Muir; Hon. V. Bugeja; officers' mess, 2-22nd Regiment; Mr. W. A. Dewar; Admiral Superintendent; Messrs. P. Stuart & Co.; Messrs. Degiorgio & Muscat; Hon. Dr. Sciortino; Malta Union Club; Garrison Library; Messrs. Eynaud & Co.; Messrs. Petrocochino & Co.; Mr. C. A. Wright; Hon. Dr. Torreggiani; Messrs. Glass, Elliot, & Co.; officers' mess, 1-22nd Regiment; *Times of India*, Bombay; Mr. G. Ellul; officers' mess, 2-8th Regiment; Mr. A. Terreni; Sergeant Robertson, 2-4th Regiment; Mr. Ramiro Barbaro, and Colonel McIver.

"*Subscribers who have left the Island.*—Major Newdigate, R.B.; officers' mess, 2-15th Regiment; officers' mess, 1-25th Regiment; Dr. R. Turner; and Rev. Mr. Fox.

"*Subscribers who have discontinued.*—Messrs. Smith & Co.; Messrs. Ferro & Co.; Mr. S. Baldacchino; Mr. O. F. Gollcher; Mr. G. Montano; Mr. E. Zammit; Mr. A. Duncan; Hon. Dr. Mifsud; Messrs. Woodhouse & Co.; Mr. G. Bonavia; Mr. T. Sceberras; Messrs. R. Duckworth & Co.; and Messrs. B. Tagliaferro & Sons."

ON RADIATION THROUGH THE EARTH'S ATMOSPHERE.*

BY JOHN TYNDALL, ESQ., F.R.S.

NOBODY ever obtained the idea of a line from Euclid's definition that it is length without breadth. The idea is obtained from a real physical line drawn by a pen or pencil, and therefore possessing width; the idea being afterwards brought, by a process of abstraction, more nearly into accordance with the conditions of the definition. So also with regard to physical phenomena; we must help ourselves to a conception of the invisible by means of proper images derived from the visible, afterwards purifying our conceptions to the needful extent. Definiteness of conceptions, even though at some expense to delicacy, is of the greatest utility in dealing with physical phenomena. Indeed, it may be questioned whether a mind trained in physical research can at all enjoy peace without having made clear to itself some possible way of conceiving of those operations which lie beyond the boundaries of sense, and in which sensible phenomena originate.

When we speak of radiation through the atmosphere, we ought to be able to affix definite physical ideas both to the term atmosphere and the term radiation. It is well known that our atmosphere is mainly composed of the two elements, oxygen and nitrogen. These elementary atoms may be figured as small spheres scattered thickly in the space which immediately surrounds the earth. They constitute about 99½ per cent. of atmosphere. Mixed with these atoms we have others of a totally different character: we have the molecules, or atomic groups of carbonic acid, of ammonia, and of aqueous vapour. In these substances diverse atoms have coalesced to form little systems of atoms. The molecule of aqueous vapour, for example, consists of two atoms of hydrogen united to one of oxygen, and they mingle as little triads among the monads of oxygen and nitrogen, which constitute the great mass of the atmosphere.

These atoms and molecules are separate, but in what sense? They are separate from each other in the sense in which the individual fishes of a shoal are separate. The shoal of fish is embraced by a common medium, which connects the different members of the shoal, and renders intercommunication between them possible. A medium also embraces our atoms; within our atmosphere exists a second and a finer atmosphere, in which the atoms of oxygen and nitrogen hang like suspended grains. This finer atmosphere unites not only atom with atom, but star with star; and the light of all suns, and of all stars, is in reality a kind of music propagated through this interstellar air. This image must be clearly seized, and then we have to advance a step. We must not only figure our atoms suspended in this medium, but we must figure them vibrating in it. In this motion of the atoms consists what we call their heat. "What is heat in us," as Locke has perfectly expressed it, "is in the body heated nothing but motion." Well, we must figure this motion communicated to the medium in which the atoms swing, and sent in ripples through it with inconceivable velocity to the bounds of space. Motion in this form, unconnected with ordinary matter, but speeding through the interstellar medium, receives the name of radiant heat; and, if competent to excite the nerves of vision, we call it light.

Aqueous vapour was defined to be an invisible gas. Vapour was permitted to issue horizontally with considerable force from a tube connected with a small boiler. This track of the cloud of condensed steam was vividly illuminated by the electric light. What was seen, however, was not vapour, but vapour condensed to water. Beyond the visible end of the jet the cloud resolved itself into true vapour. A lamp was placed under the jet at various points; the cloud was cut sharply off at that point; and when the flame was placed near the efflux orifice, the cloud entirely disappeared. The heat of the lamp completely prevented precipitation. This same vapour was condensed and congealed on the surface of a vessel containing a freezing mixture, from which it was scraped in quantities sufficient to form a small snowball. The beam of the electric lamp, moreover, was sent through a large receiver placed on an air-pump. A single stroke of the pump caused the precipitation of the aqueous vapour within, which became beautifully illuminated by the beam; while, upon a screen behind, a richly-coloured halo due to diffraction by the little cloud within the receiver flashed forth.

The waves of heat speed from our earth through our atmosphere towards space. These waves dash in their passage against the atoms of oxygen and nitrogen, and against the molecules of aqueous vapour. Thinly scattered as these latter are, we might naturally think meanly of them as barriers to the waves of heat. We might imagine that the wide spaces between the vapour molecules would be an open door for the passage of the undulations; and that if those waves were at all intercepted, it would be by the substances which form 99½ per cent. of the whole atmosphere. Three or four years ago, however, it was found by the speaker that this small modicum of aqueous vapour intercepted fifteen times the quantity of heat stopped by the whole of the air in which it was diffused. It was afterwards found that the dry air then experimented with was not perfectly pure, and that the purer the air became the more it approached the character of a vacuum, and the greater, by comparison, became the action of the aqueous vapour. The vapour was found to act with 30, 40, 50, 60, 70 times the energy of the air in which it was diffused; and no doubt was entertained that the aqueous vapour of the air which filled the Royal Institution theatre during the delivery of the discourse absorbed 90 or 100 times the quantity of radiant heat which was absorbed by the main body of the air of the room.

Looking at the single atoms, for every 200 of oxygen and nitrogen there is about 1 of aqueous vapour. This 1, then, is 80 times more powerful than the 200; and hence, comparing a single atom of oxygen or nitrogen with a single atom of aqueous vapour, we may infer that the action of the latter is 16,000 times that of the former. This was a very astonishing result, and it naturally excited opposition, based on the philosophic reluctance to accept a result so grave in consequences before testing it to the uttermost. From such opposition a discovery, if it be worth the name, emerges with its fibre strengthened, as the human character gathers force from the healthy antagonisms of active life. It was urged that the result was, on the face of it, improbable; that there were, moreover, many ways of accounting for it without ascribing so enormous a comparative action to aqueous vapour. For example, the cylinder which contained the air in which these experiments were made was stopped at its ends by plates of rock-salt, on account of their transparency to radiant heat. Rock-salt is hygroscopic: it attracts the moisture of the atmosphere. Thus, a layer of brine readily forms on the surface of a plate of rock-salt; and it is well known that brine is very impervious to the rays of heat. Illuminating a polished

* A paper read at the Royal Institution.

plate of salt by the electric lamp, and casting, by means of a lens, a magnified image of the plate upon a screen, the speaker breathed through a tube for a moment on the salt; brilliant colours of thin plates (soap-bubble colours) flashed forth immediately upon the screen—these being caused by the film of moisture which overspread the salt. Such a film, it was contended, is formed when undried air is sent into the cylinder; it was, therefore, the absorption of a layer of brine which was measured, instead of the absorption of aqueous vapour.

This objection was met in two ways:—1st. By showing that the plates of salt when subjected to the strictest examination show no trace of a film of moisture. 2ndly. By abolishing the plates of salt altogether, and obtaining the same results in a cylinder open at both ends.

It was next surmised that the effect was due to the impurity of the London air, and the suspended carbon particles were pointed to as the cause of the opacity to radiant heat. This objection was met by bringing air from Hyde-park, Hampstead-heath, Primrose-hill, Epsom Downs, a field near Newport in the Isle of Wight, St. Catharine's Down, and the sea-beach near Black Gang Chine. The aqueous vapour of the air from these localities intercepted at least seventy times the amount of radiant heat absorbed by the air in which the vapour was diffused. Experiments made with smoky air proved that the suspended smoke of the atmosphere of West London, even when an east wind pours over it—the smoke of the city, exerts only a fraction of the destructive powers exercised by the transparent and impalpable aqueous vapour diffused in the air.

The cylinder which contained the air through which the calorific rays passed was polished within, and the rays which struck the interior surface were reflected from it to the thermo-electric pile which measured the radiation. The following objection was raised:—You permit moist air to enter your cylinder; a portion of this moisture is condensed as a liquid film upon the interior surface of your tube; its reflective power is thereby diminished; less heat therefore reaches the pile, and you incorrectly ascribe to the absorption of aqueous vapour an effect which is really due to diminished reflection of the interior surface of your cylinder.

But why should the aqueous vapour so condense? The tube within is warmer than the air without, and against its inner surface the rays of heat are impinging. There can be no tendency to condensation under such circumstances. Further, let five inches of undried air be sent into the tube—that is, one-sixth of the amount which it can contain. These five inches produce their proportionate absorption. The driest day on the driest portion of the earth's surface would make no approach to the dryness of our cylinder when it contains only five inches of air. Make it 10, 15, 20, 25, 30 inches: you obtain an absorption exactly proportional to the quantity of vapour present. It is next to a physical impossibility that this could be the case if the effect were due to condensation. But lest a doubt should linger in the mind, not only were the plates of rock-salt abolished, but the cylinder itself was dispensed with. Humid air was displaced by dry, and dry air by humid in the free atmosphere; the absorption of the aqueous vapour was here manifest, as in all the other cases.

No doubt, therefore, can exist of the extraordinary opacity of this substance to the rays of obscure heat, and particularly such rays as are emitted by the earth after it has been warmed by the sun. It is perfectly certain that more than 10 per cent. of the terrestrial radiation from the soil of England is stopped within ten feet of the surface of the soil. This one fact is sufficient to show the immense influence which this newly-discovered property of aqueous vapours must exert on the phenomena of meteorology.

This aqueous vapour is a blanket more necessary to the vegetable life of England than clothing is to man. Remove for a single summer night the aqueous vapour from the air which overspreads this country, and you would assuredly destroy every plant capable of being destroyed by a freezing temperature. The warmth of our fields and gardens would pour itself unrequited into space, and the sun would rise upon an island held fast in the iron grip of frost. The aqueous vapour constitutes a local dam, by which the temperature at the earth's surface is deepened; the dam, however, finally overflows, and we give to space all that we receive from the sun.

The sun raises the vapours of the equatorial ocean; they rise, but for a time a vapour screen spreads above and around them. But the higher they rise, the more they come into the presence of pure space; and when, by their levity, they have penetrated the vapour screen which lies close to the earth's surface what must occur?

It has been said that, compared atom for atom, the absorption of an atom of aqueous vapour is 16,000 times that of air. Now the power to absorb and the power to radiate are perfectly reciprocal and proportional. The atom of aqueous vapour will therefore radiate with 16,000 times the energy of an atom of air. Imagine, then, this powerful radiant in the presence of space, and with no screen above it to check its radiation. Into space it pours its heat, chills itself, condenses, and the tropical torrents are the consequence. The expansion of the air, no doubt, also refrigerates it; but in accounting for these deluges, the chilling of the vapour by its own radiation must play a most important part. The rain quits the ocean as vapour; it returns to it as water. How are the vast stores of heat set free by the change from the vaporous to the liquid condition disposed of? Doubtless in great part they are wasted by radiation into space. Similar remarks apply to the cumuli of our latitudes. The warmed air, charged with vapour, rises in columns, so as to penetrate the vapour screen which hugs the earth; in the presence of space the head of each pillar wastes its heat by radiation, condenses to a cumulus, which constitutes the visible capital of an invisible column of saturated air.

Numberless other meteorological phenomena receive their solution by reference to the radiant and absorbent properties of aqueous vapour. It is the absence of this screen, and the consequent copious waste of heat, that causes mountains to be so much chilled when the sun is withdrawn. Its absence in Central Asia renders the winter there almost unendurable; in Sahara the dryness of the air is sometimes such, that though during the day "the soil is fire and the wind is flame," the chill at night is painful to bear. In Australia also the thermometric range is enormous, on account of the absence of this qualifying agent. A clear day and a dry day, moreover, are very different if it is charged with aqueous vapour, and on such occasions great chilling cannot occur by terrestrial radiation. Sir John Leslie and others have been perplexed by the varying indications of their instruments on days equally bright; but all these anomalies are completely accounted for by reference to this newly-discovered property of transparent aqueous vapour. Its presence would check the earth's loss; its absence, without sensibly altering the transparency of the air, would open wide a door for the escape of the earth's heat into infinitude.

ANECDOTES OF THE TELEGRAPH.

READING BY SOUND.—The substitution of reading by sound, instead of by sight, is a matter of very great importance to the proprietors of telegraph companies as well as the public: to the former because it saves expense, and to the latter because it ensures greater safety; and, finally, to both for the same reasons, for the interests of the proprietors and the public are very closely connected. We shall not pretend to say to whom is entitled the credit of having first discovered the idea of reading by sound; and if we could it would be a matter of no importance, for no one with a good idea of time could be within hearing of a Morse register a day without being aware of its peculiar adaptedness for this use. The first time, however, we saw any one read in this manner was in the winter of 1846-7 in New York. The lines were broken, and Mr. O. E. Wood and ourself were sent out to repair them. Mr. Wood carried a small electro-magnet in his hand, and when we reached Harlem-bridge he disconnected the line-wire, and attached it to one end of the helix-wire, and then, uncoiling a dozen or two feet of iron wire, dropped one end of it in the river, and with the other commenced tapping upon the other extremity of the helix-wire. To our infinite astonishment we saw the lever fly backward and forward, and presently, when he had stopped writing, he received a reply from the office in New York. He gave us the questions and answers as he received and sent them; and, although we have a thousand times since accomplished the same feat, the conversation and the occurrence are still indelibly fixed in our memory. No trick of legerdemain performed by the most successful necromancer has ever been able to excite so much interest in our mind as this.

READING BY SHOCKS.—There is, however, still another mode of receiving intelligence in connection with the Morse lines besides those already described—namely, by means of the passage of shocks through the system. This, we presume, has often been accomplished by different persons, although we have not been knowing to the fact. Mr. Milliken, of the American Telegraph-office in Boston, assures us that he once read the greater part of a despatch as it was passing over the wires between Boston and Portland, and that he heard the Portland operator respond "O K" (all right) to

it, while he was seated upon the draw at Mystic River-bridge, and held the end of a wire in each hand, thus passing the current through his body, and enabling them to read the letters by the duration and number of the shocks which he received. We have succeeded upon several occasions in receiving messages in this manner when we have been at a distance from an office, and wished to obtain information in regard to the state of the line. Not long since we had been annoyed upon one of our wires by a very bad earth-current, and none of the repairers being able to find the difficulty, we instituted a search for it. Finally, upon arriving at Nepouset, we opened the circuit at the draw, and inquired of the Boston operator, by touching the ends of the wire together in the proper time, if the earth-current was between us and the Boston office, or beyond. This he would at once tell by my opening the circuit—disconnecting the wires; if he got any magnetism when the wires were disconnected, then the earth-current was between us and the office; if he got none, then the trouble was beyond. This was important for us to know. He replied that he did get an earth-current when we opened the circuit. We asked if it was very strong. "Yes," he replied, "nearly as strong as when you close." All this, the reader will understand, we received through our system, and interpreted by the duration and number of the shocks. "There is trouble also upon the New Bedford wire," said he; "I have not had any circuit for nearly half-an-hour." We then sent an order for a line repairer to go out at once and repair that line, and then recommenced our investigations into the location of the earth-current, which we shortly afterwards succeeded in finding.

Spiritual Interruptions!—We have previously mentioned that the earth serves as a return wire. The earth, in fact, from its immense conducting surface, constitutes the best conductor—better than all minerals, for its resistance to the passage of an electric current has been found to be null. It being the same thing, in fact, to put the two ends of the wire into connection with the earth as to bring them together. This, as may be imagined, is of vast importance in the economy of working telegraph lines, as one wire in every circuit is thus saved; but there are sometimes very provoking consequences resulting from this cause—namely, the loss of current by earth circuit or "escape." An occurrence of this kind happened upon the line between Boston and Salem some months since, which baffled for weeks the most careful research of experienced repairers. The earth current came on at precisely seven o'clock p.m., and was off at the commencement of business in the morning; therefore, there was only from seven p.m. to eight a.m. when there was any opportunity of finding it. Five men were despatched over the road every day with strict injunctions to watch every inch of the wire, but still they reported that nothing could be found. It looked mysterious. Had the spirits anything to do with it? They had never yet troubled the telegraph, but there must be a beginning for all things—was this the beginning? We strongly suspected that it was. One afternoon we went to Salem ourself, and remained in the office from half-past six to seven o'clock. We would see if it would come on while we were there. Seven o'clock arrived, no earth-current; one minute past, none; three, none. We began to feel encouraged; perhaps it had "played out." The train left at 7.15; we hoped to leave in that, with the knowledge that all was right—7.4, no earth-current; 7.5, it is on again. We were in for it, and we immediately started for a personal solution of the difficulty. Upon walking down the track a few rods we found the "spirit" in the shape of an iron switch-rod, which had been put up about four weeks before to switch off the Marblehead track at seven o'clock every morning, and *which was switched on at precisely seven o'clock each afternoon.* Upon this occasion the switchman had been five minutes late. He said he noticed when he switched it on that it touched the wires, but he did not know that it would do any damage, as it was only iron. Thus ended our first assault upon the spirits.—*Prescott.*

Six Bell-Ringers Killed by Lightning.—A few days ago, says a Tyrolese paper, a thunderstorm discharged its fury on the village of Worgel, in the Valley of the Inn. True sons of the holy church, the villagers at once flocked to the steeple to attract their saint's attention by ringing the bells; and this the more readily as they had the good luck of numbering among them a bell reported miraculous, and which had been long renowned for its efficacy in case of danger from fire or water. But the laws of Nature do not always agree with the superstitions of the church. The electric fluid being attracted by the huge piece of metal swaying to and fro, the lightning came down upon the ringers, and killed six of them on the spot.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

VII.

A.D. 1816.—Mr. F. Ronalds invented his electric telegraph in 1816. Tension electricity was employed. "The wires used were laid under-ground as well as suspended in the air. A pith-ball electrometer, hung before a clock movement, enabled the letters on a dial to be read off." (See Highton's *Electric Telegraph*, p. 39.)

A.D. 1818.—Dr. A. Ure, in 1818, submitted the body of a man who had been hanged, immediately after the execution, to the action of a galvanic battery of 270 pairs of copper and zinc plates. One of the electrodes was, by means of an incision, placed in contact with the spinal marrow, whilst the other was applied to the sciatic nerve, which had also been laid bare. Immediately all the limbs of the body were agitated by convulsive movements, and a wonderful likeness to the actions of various organs of the body in life was produced, much to the terror of the spectators. (See De la Rive's *Treatise on Electricity*, Vol. II., pp. 489, 490; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 197.)

A.D. 1819.—Professor Oersted, of Copenhagen, in a work published in 1807, proposed "to try whether electricity, in its latent state, will not affect the magnetic needle;" and, at the close of the year 1819, he found that, "that end of the needle which is situated next to the negative side of the" [galvanic?] "battery, or towards which the current of positive electricity is flowing, immediately moves to the westward." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 1; also *Library of Useful Knowledge*, Electro-magnetism, p. 4.)

A.D. 1819.—Hare's "calorimotor" was constructed in 1819. In this galvanic battery the zinc plates were in flat copper cases. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 222; also Gmelin's *Handbook of Chemistry*, Vol. I., pp. 409, 410.)

A.D. 1820.—M. Ampère, at a meeting of the Royal Academy on September 18, 1820, proved that the voltaic pile itself acted in the same manner on the magnetic needle as the connecting wire, and produced to the meeting a "galvanometer." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 5.)

A.D. 1820.—M. Ampère, on September 25, 1820, announced the "fact of the attraction and repulsion of two wires connecting the poles of a" [galvanic?] "battery; and showed that the magnetic needle which had previously been used to prove the magnetic attractions and repulsions of the wire, could be replaced by another connecting wire like the first." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 5.)

A.D. 1820.—M. Arago, on September 25, 1820, "stated to the Royal Academy of Sciences that he had ascertained the attraction of iron filings by the connecting wire of the" [galvanic?] "battery, exactly as by a magnet." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 6.)

A.D. 1820.—M. Arago, about the end of September, 1820, magnetized a sewing-needle permanently by the galvanic current. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 6.)

A.D. 1820.—M. Ampère, in September, 1820, found a spiral or helical arrangement of the galvanic conducting-wire most advantageous in magnetizing needles. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 6.)

A.D. 1820.—M. Boisgeraud, on October 9, 1820, read a paper to the Royal Academie of Sciences, in which he proposed to ascertain the conducting power of different substances by placing them in the galvanic circuit, together with Ampère's galvanometer. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 6.)

A.D. 1820.—M. Ampère, on October 30, 1820, read an account to the Royal Academy of his method of proving the action of terrestrial magnetism upon galvanic currents. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 7.)

A.D. 1820.—MM. Biot and Savart, on October 30, 1820, read a memoir to the Academy of Sciences, in which it was demonstrated by oscillations of the magnetic needle, that the action of a galvanic conducting-wire upon it (the needle) was "in the inverse ratio of the simple distance." (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, pp. 4 and 7.)

A.D. 1820.—M. Arago, on November 6, 1820, announced that common or static electricity produced the same effects in magnetizing iron and steel as voltaic electricity. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 7.)

A.D. 1820.—Ampère, on November 6, 1820, perfectly imitated a magnet by a helical galvanic conducting wire. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, pp. 7, 8.)

A.D. 1820.—Schweigger, in 1820, invented his galvanometer. (See *Encyclopædia Britannica*, 7th edition, art. Voltaic Electricity, p. 687.)

A.D. 1820.—Sir Humphrey Davy, about the close of the year 1820, caused the rotation of an arc of electric light, by the proximity of the poles of a powerful permanent magnet. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, pp. 9, 10.)

A.D. 1820.—Ampère invented his telegraphic arrangement in 1820: He "employed the magnetic needle, the coil of wire, and the galvanic battery, and proposed the use of as many wires as letters or signals to be indicated." (See Highton's *Electric Telegraph*, p. 39.)

A.D. 1820.—Sir William Snow Harris, in 1820, supplied sea-going vessels with lightning-conductors. (See *Encyclopædia Britannica*, 8th edition, art. Electricity, p. 610.)

A.D. 1820.—Bohnenberger, in 1820, invented his electroscope. This instrument consists of a gold leaf suspended between the opposite poles of two dry piles; it is thus made not only to show the presence, but also the kind of electricity possessed or developed by the body under examination, and is extremely sensitive in its indications. (See Noad's *Manual of Electricity*, p. 30; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 54-56.)

A.D. 1821.—Faraday, in 1821, discovered the electro-magnetic rotative force developed in a magnet by a wire-conducting galvanic electricity, and in a conducting wire by a magnet. He also demonstrated the ability of terrestrial magnetism to rotate a conducting wire. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 12.)

A.D. 1821.—Professor Cumming, in April, 1821, invented a galvanometer in which a conducting wire was disposed in a circle or square of two or more coils, and the terrestrial direction of the needle (placed within the coils) was neutralized. In certain experiments he found the tangent of a needle's deviation varied inversely as the distance of the conducting wire from the magnetic needle; also that, when the battery plates were placed at different distances from one another, the "tangent of deviation varied inversely as the square root of the distances of the plates." Professor Cumming, with the assistance of Dr. Clarke and Mr. Lunn, produced "electro-magnetic effects from the electricity of the atmosphere, by the usual apparatus, an electrical kite." (See the *Transactions of the Cambridge Philosophical Society*, 1821; also *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, pp. 14, 15.)

A.D. 1821.—Hare's "deflagrator" was constructed in 1821. This galvanic arrangement consisted of eighty coils of zinc and copper plates immersed in eighty separate vessels. (See *Encyclopedia Metropolitana*, Vol. IV., art. Galvanism, pp. 176 and 222; also Gmelin's *Handbook of Chemistry*, Vol. I., pp. 409, 410.)

A.D. 1823.—M. Seebeck discovered thermo-electricity in 1823. His first experiment was as follows:—A kind of arc was made of a plate of copper soldered to a bar of bismuth, in the interior of which a magnetic needle was pivoted; a deflection of the needle was produced by heating either of the soldered junctions. (See De la Rive's *Treatise on Electricity*, Vol. II., p. 535.)

A.D. 1823.—Professor Cumming, in 1823, ascertained that the unequal distribution of heat was the cause of thermo-electricity, and made a table of positive and negative thermo-electrics. About this period Van Zuylen, Dr. Van Beek, and Professor Moll, of Utrecht, extended Seebeck's experiments. (See *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, pp. 20-26; also the *Transactions of the Cambridge Philosophical Society*, 1823.

A.D. 1823.—Pepys, in 1823, constructed the galvanic battery for the London Institution. It was formed of a single pair of plates (copper and zinc), coiled like a double ribbon round a wooden cylinder, and prevented from coming into contact by means of horsehair ropes. (See *Practical Mechanic and Engineer's Magazine*, February, 1842, p. 191; also *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, pp. 176 and 222.)

A.D. 1824.—Sir Humphrey Davy, in 1824, applied the principles of galvanic electricity to prevent the corrosion of the copper sheathing of ships by sea-water. Strips of zinc were affixed to the copper sheathing for this purpose; the copper was thereby protected at the expense of the zinc, but, in practice, sea-weed and shell-fish were found to adhere to the protected surface. (See *Encyclopædia Metropolitana*, Vol. IV., art. Galvanism, p. 222; also Bakewell's *Electric Science*, p. 35.)

A.D. 1824.—De la Rive described the sine galvanometer in 1824. (See De la Rive's *Treatise on Electricity*, Vol. I., p. 334.)

A.D. 1824.—Professor Barlow, in 1824, established the fact that the galvanic fluid in a conducting wire acts on the magnetic fluid in a magnetized needle with a force varying inversely as the square of the distance. He also proved that magnetic poles tend to place themselves at right angles to electric poles, and *vice versâ*, by the action of a tangential force. (See *An Essay on Magnetic Attractions*, 2nd edition, 1824; also *Encyclopædia Metropolitana*, Vol. IV., art. Electro-magnetism, p. 15.)

A.D. 1826.—Pohl, about the year 1826, made the following galvanic arrangement:—"One zinc and seven copper plates are separated from one another by seven layers of a moist conductor which does not surround them, but merely touches their surfaces." The zinc at one end is connected by a metallic arc with the copper, No. 7, at the opposite end; No. 1 copper plate is similarly connected with No. 6; No. 2 with No. 5; and No. 3 with No. 4. "An electric current, sensible to an interposed galvanometer, goes through all the arcs, through the first and third in one direction, through the second and forth in the opposite direction. The current in the first arc is the strongest, that of the second weaker, and that of the fourth weakest of all." (See Gmelin's *Handbook of Chemistry*, Vol. I., p. 408.)

A.D. 1826.—Sir Humphrey Davy, in his Bakerian Lecture in 1826, stated that "zinc in amalgamation with mercury is positive with respect to pure zinc" in a galvanic arrangement. (See Sturgeon's *Annals of Electricity, Magnetism, and Chemistry*, Vol. I., January, 1837, p. 81.)

A.D. 1826.—M. Leopold Nobili, of Reggio, in the year 1826, discovered metallo-chromy. This phenomenon is known by the name of "Nobilli's rings," and is produced by the electrolysis of a solution of acetate of lead, using a platinum plate as a positive pole and a platinum wire as a negative pole. The deposit takes place on the positive plate, and consists of concentric coloured rings of peroxide of lead. Mr. Gassiot used for this experiment a perforated card placed over a polished steel positive plate, and a negative plate of copper covering the whole. (See Sturgeon's *Lectures on Galvanism*, pp. 197, 198.)

A.D. 1827.—Ohm, in 1827, put forward the following celebrated formulæ relating to the *quantity* of the galvanic current:—"1. *For a conductor into whose extremities the two electricities flow with a given tension:* Let A be the electrical tension; K the conducting power of the wire or other conductor; *w* the surface of its transverse section; L its length; Q the quantity of current; then $Q=\frac{AKw}{L}$." "2. *For a simple galvanic circuit:* Let A be the electro-motive power of the circuit (or the tension?), R the resistance which the current meets with in the circuit itself. This is the resultant of the following individual resistances:—*a.* Resistance of the two metallic plates which the current has to traverse;—*b.* Resistance of the liquid through which, according to the ordinary view, the current passes." "To this Fechner and Poggendorff add *c*, the resistance of transition,—*i.e.* the resistance which exists to the passage of the electric current from the metal to the liquid, and conversely. Also let *r* be the resistance of the conductor which unites the two metals, and Q the quantity of the electric current which enters it; then $Q=\frac{A}{R+r}$; therefore $A = Q\,(R + r)$." "3. *For the galvanic battery: n* denoting the number of united simple circuits, $Q=\frac{nA}{nR+r}$." (See Gmelin's *Handbook of Chemistry*, Vol. I., pp. 414, 415.)

A.D. 1827.—M. Savary, in 1827, pointed out that the intensity, and even the direction, of the magnetization produced upon a steel needle by a discharge of fractional electricity transmitted through a rectilinear wire, depends upon the distance of the needle from this wire; also that the magnetic intensity does not diminish as the distance from the wire increases, but there are points of maximum and minimum intensity. He produced similar results by discharges of successively increasing intensity through a helix. M. Savary found that insulated conducting (but non-magnetic) envelopes to the needle, placed within the helix and insulated from it, diminished the magnetizing power of the helix. (See De la Rive's *Treatise on Electricity*, Vol. I., pp. 281-287, also Vol. II., p. 889.)

A.D. 1827.—Sir William Snow Harris, in 1827, invented the thermo-electrometer. (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 89.)

A.D. 1828.—Mr. Kemp, in 1828, employed fluid amalgam of zinc in galvanic batteries. (See Sturgeon's *Annals of Electricity, Magnetism, and Chemistry*, Vol. I., January, 1837, pp. 81-88.)

A.D. 1828.—Dr. Farré Palaprat, in 1828, published a translation of a work of Labaume. The medical effects of electricity are

brought about in this instance by galvanism. Dr. Fabré Palaprat "employed a platinum wire heated by a voltaic battery, in order to produce moxas." (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 589 and 687.)

A.D. 1828.—Mr. Green, in a work published in 1828, investigated the subject of the distribution of electricity, mathematically, and proved that an infinite number of forms of conductors may be invented so that the distribution of electricity in equilibrium may be expressed in finite algebraic terms. (See *Encyclopædia Britannica*, 8th edition, art. Electricity, pp. 533, 534.)

A.D. 1828.—Tribaoillet, in 1828, invented his electric telegraph; it "required but one wire, and this was buried in the earth. A galvanic battery and a galvanoscope were employed." (See Highton's *Electric Telegraph*, p. 39.)

A.D. 1829.—Becquerel, in 1829, made public a double-fluid galvanic battery, consisting of copper, a salt of copper, dilute sulphuric acid or sulphate of zinc, and zinc. (See *Practical Mechanic and Engineers' Magazine*, September, 1842, p. 484.)

A.D. 1829.—Becquerel, in 1829, used membranous diaphragms in voltaic batteries. He also used porcelain clay, wetted with a solution of sea-salt, and plaster of Paris. (See *Practical Mechanic and Engineers' Magazine*, November, 1842, p. 43.)

A.D. 1830.—Mr. Sturgeon, in 1830, published his method of using amalgamated rolled zinc plates as positive plates in galvanic batteries. His cast-iron single-fluid galvanic battery was invented about this time. (See Sturgeon's *Lectures on Galvanism*, pp. 135-137.)

A.D. 1830.—Mr. Fox, of Falmouth, in 1830, published his researches respecting the electricity of metalliferous veins. (See *Philosophical Transactions*, 1830, p. 399.)

A.D. 1830.—Dr. Ritchie, in 1830, put forward his torsion galvanometer. (See *Encyclopædia Britannica*, 7th edition, art. Voltaic Electricity, p. 688.)

A.D. 1830.—M. Rayer "introduced, since 1830, during his service at the Hospital of Charity, a trough" [galvanic?] "battery, and made it serve in the treatment of all kinds of paralysis." (See De la Rive's *Treatise on Electricity*, Vol. III., p. 592.)

A.D. 1831.—Dr. Faraday, in 1831, produced an electric spark by the sudden separation of a coiled keeper from a permanent magnet. He also, in 1831, found an electric current to exist in a copper plate rotated between the poles of a magnet. (See Bakewell's *Electric Science*, pp. 39, and 140, 141.)

A.D. 1831.—MM. Andral and Ratier, in 1831, published an article in the Dictionary of Medicine and Practical Surgery which gives a summary of the work of M. Andrieux on medical electricity. The various kinds of electricity are herein proposed as extremely powerful physical agents. (See De la Rive's *Treatise on Electricity*, Vol III., pp. 591, 592.)

A.D. 1831.—Dr. Faraday, in 1831, discovered the existence of the electric current induced in a hollow coil of wire when a steel permanent magnet is introduced into or withdrawn from the coil. An electro-magnet was afterwards substituted for the permanent magnet with even greater success. (See Bakewell's *Electric Science*, p. 39.)

A.D. 1831.—Professor Henry, of Princeton, United States, in 1831, suggested the application of electro-magnetic force to motive power. (See *Encyclopædia Britannica*, 7th. edition, art. Voltaic Electricity, p. 687.)

A.D. 1832.—Schilling invented his electric telegraph in 1832. He "employed five magnetic needles and had also a mechanical alarum." In another telegraph he only used one wire and one needle. (See Highton's *Electric Telegraph*, p. 39.)

A.D. 1832.—Schilling, in 1832, placed the telegraph magnetic needles vertical. (See Highton's *Electric Telegraph*, p. 137.)

A.D. 1832.—Schilling, in 1832, used a weight, which was caused to fall by a current of electricity, to sound a bell. (See Highton's *Electric Telegraph*, p. 137.)

A.D. 1832.—Dr. Botto, of Turin, in 1832, made a thermo-electric battery of platinum and iron. (See Noad's *Lectures on Electricity*, p. 426.)

A.D. 1832.—M. Pixii, in 1832, constructed his magneto-electric machine. In this arrangement a horseshoe permanent magnet rotated in front of a coiled keeper. (See Highton's *Electric Telegraph*, p. 17; also De la Rive's *Treatise on Electricity*, Vol. I., p. 373.)

A.D. 1832.—Salvator Dal Negro, in November, 1832, published a paper in which he explained the method adopted by him of applying electro-magnetism to move machines. (See *Practical Mechanic and Engineers' Magazine*, November, 1842, p. 48.)

ON BOILING WATER.

By W. Grove, Esq., Q.C., F.R.S., M.R.I.

A paper by M. Donny (*Mémoires de l'Académie Royale de Bruxelles*, 1843,) makes known the fact that in proportion as water is deprived of air, the character of its ebullition changes, becoming more and more abrupt, and boiling like sulphuric acid with *soubresauts*, and that between each burst of vapour the water reaches a temperature above its boiling point. To effect this, it is necessary that the water be boiled in a tube with a narrow orifice, through which the vapour issues; if it be boiled in an open vessel it continually re-absorbs air and boils in the ordinary way.

In my experiments on the decomposition of water by heat, I found that with the oxyhydrogen gas given off from ignited platinum plunged into water, there was always a greater or less quantity of nitrogen mixed; this I could never entirely get rid of, and was thus led into a more careful examination of the phenomenon of boiling water, and set before myself this problem—what will be the effect of heat on water, perfectly deprived of air or gas?

Two copper wires were placed parallel to each other through the neck of a Florence cask, so as nearly to touch the bottom; joining the lower ends of these was a fine platinum wire, about an inch and a-half long, and bent horizontally into a curve. Distilled water, which had been well boiled and cooled under the receiver of an air-pump, was poured into this flask so as to fill about one-fourth of its capacity. It was then placed under the receiver of an air-pump, and one of the copper wires brought in contact with a metallic plate covering the receiver, the other bent backwards over the neck of the flask and its ends made to rest on the pump-plate. By this means, when the terminal wires from a voltaic battery were made to touch the one, the upper and the other lower plate, the platinum wire would be heated, and the boiling continued indefinitely in the vacuum of a very excellent air-pump. The effect was very curious. The water did not boil in the ordinary manner, but at intervals a burst of vapour took place, dashing the water against the sides of the flask, some escaping into the receiver. (There was a projection at the central orifice of the pump-plate to prevent this overflow getting into the exhaustion tube.)

After each sudden burst of vapour, the water became perfectly tranquil, without a symptom of ebullition until the next burst took place. These sudden bursts occurred at measured intervals, so nearly equal in time that, had it not been for the escape from the flask at each burst of a certain portion of water, the apparatus might have served as a time-piece.

This experiment, though instructive, did not definitely answer the question I had proposed, as I could not, of course, ascertain whether there was some minute residuum of gas which would form the nucleus of each ebullition, and I proceeded with others. A tube of glass, 5 feet long and $\frac{1}{10}$ths of an inch internal diameter, was bent into a V-shape; into one end a loop of platinum wire was hermetically sealed with great care, and the portion of it in the interior of the tube was platinized. When the tube had been washed, distilled water, which had been well purged of air as before, was poured into it to the depth of 8 inches, and the rest of the tube filled with olive oil; when the V was inverted, the open end of the tube was placed in a vessel of olive oil, so that there would be 8 inches of water resting on the platinum wire, separated from the external air by a column of 4 feet 4 inches of oil. The projecting extremities of the platinum wire were now connected with the terminals of a voltaic battery, and the water heated; some air was freed, and ascended to the level of the tube—this was made to escape by carefully inverting the tube so as not to let the oil mix with the water—and the experiment continued. After a certain time the boiling assumed a uniform character, not by such sudden bursts as in the Florence flask experiment, but with larger and more distinct bursts of ebullition than in its first boiling.

The object of platinizing the wire was to present more points for the ebullition, and to prevent *soubresauts* as much as possible.

The experiment was continued for many hours, and, in some repetitions of it, for days. After the boiling had assumed a uniform character, the progress of the vapour was carefully watched, and as each burst of vapour condensed in the oil, which was kept cool, it left a minute bead of gas, ascending through the oil to the bend of the tube: a bubble was formed here which did not seem at all absorbed by the oil. This was analysed by a eudiometer, which I will presently describe, and proved to be nitrogen. The beads of gas, when viewed through a lens and micrometer scale at the same

height in the tube, appeared as nearly as may be of the same size. No bubble of vapour was condensed completely, or without leaving this residual bubble. The experiment was frequently repeated, and continued until the water was so nearly boiled away that the oil, when disturbed by the boiling, nearly touched the platinum wire; here it was necessarily stopped.

To avoid any question about the boiling being by electrical means, similar experiments were made with a tube, without a platinum wire, closed at its extremity, and the boiling was produced by a spirit lamp. The effects were the same, but the experiment was more difficult and imperfect, as the bursts of vapour were more sudden, and the duration of the intervals more irregular.

The beads of gas were extremely minute, just visible to the naked eye, but were made visible to the audience by means of the electric light.

In these experiments there was no pure boiling of water—*i.e*, no rupture of cohesion of the molecules of water itself, but the boiled, to use M. Donny's expression, by evaporation against a surface of gas.

It is hardly conceivable that air could penetrate through such a column of oil, the more so as the oil did not perceptibly absorb the nitrogen freed by the boiling water and resting in the bend of the tube. But to meet this conjectural difficulty, the following experiment was made:—A tube, 1 foot long and $\frac{3}{10}$ths of an inch internal diameter, bent into a slight angle, had a bulb three-quarters of an inch diameter, blown on it at the angle. This angle was about three inches from one end, and nine from the other. A loop of platinum wire was sealed into the shorter leg, and the whole tube and bulb filled with and immersed into mercury; water distilled, and purged of air, as before, was allowed to fill the short leg, and by carefully adjusting the inclination, the water could be boiled so as to allow bubbles to ascend into the bulb and displace the mercury. The effect was the same as with the oil experiment—no ebullition, without leaving a bead of gas; the gas collected in the bulb, and was cut off by what may be termed a valve of mercury from the boiling water, then allowed to escape, and so on. The experiment was continued for many days, and the bubbles analysed from time to time. They proved, as before, to be nitrogen, and, as before, continued indefinitely.

A similar experiment was made without the platinum wire, and though, from the greater difficulties, the experiment was not so satisfactory, the result was the same.

As the mercury of the common barometer will keep air out of its vacuum for years, if not for centuries, there could be no absorption here from the external atmosphere, and I think I am fairly entitled to conclude from the above experiments—which I believe went far beyond any that have been recorded—that no one has yet seen the phenomenon of pure water boiling, *i.e.*, of the disruption of the liquid particles of the oxyhydrogen compound so as to produce vapour which will, when condensed, become water, leaving no permanent gas. Possibly, in my experiment of the decomposition of water by ignited platinum, it may be that the sudden application of intense heat, and in some quantity, so forces asunder the molecules, that, not having sufficient nitrogen dissolved to supply them with a nucleus for evaporation, the integral molecules are severed, and the decomposition takes place. If this be so, and it seems to me by no means a far-fetched theory, there is probably no such thing as boiling, properly so called, and the effect of heat on liquid in which there is no dissolved gas may be to decompose them.

Considerations such as these led me to try the effect of boiling on an elementary liquid, and bromine occurred as the most promising one to work upon. As bromine could not be boiled in contact with water, oil, or mercury, the following plan was ultimately devised:—A tube, 4 feet long and $\frac{4}{10}$ths of an inch diameter, had a platinum loop sealed into one closed extremity; bromine was poured into the tube to the height of four inches; the open end of the tube was then drawn out to a fine point by the blow-pipe. leaving a small orifice; the bromine was then heated by a spirit-lamp, and when all the air was expelled, and a jet of bromine vapour issued from the point of the tube, it was sealed by the blow-pipe. There was then, when the bromine vapour had condensed, a vacuum in the tube above the bromine. The platinum loop was now heated by a voltaic battery, and the bromine boiled; this was continued for some time, care being taken that the boiling should not be too violent. At the end of a certain period—from half-an-hour to an hour—the platinum loop gave way, being corroded by the bromine; the quantity of this had slightly decreased. On breaking off, under water, the point of the tube, the water mounted, and showed a notable quantity of permanent gas, which on analysis proved to be pure oxygen. As much as a quarter of a cubic inch was collected at one experiment. The platinum wire which had severed at the middle, was covered with a slight black crust, which, suspecting it to be carbon, I ignited by a voltaic spark in oxygen, in a small tube over lime-water; it seemed to give a slight opalescence to the liquid, but the quantity was so small that the experiment was not relied on. No definite change was perceptible in the bromine; it seemed to be a little darker in colour, and had a few black specks floating in it, which I judged to be minute portions of the same crust which had formed on the platinum wire, and which had become detached.

The experiment was repeated with chloride of iodine, and with the same result, except that the quantity of oxygen was greater. I collected as much as half a cubic inch in some experiments, from an equal quantity of chloride of iodine; the platinum wire, however, was more quickly acted on than with bromine, and the glass of the tube around it to some extent.

Melted phosphorus was exposed to the heat of the voltaic disruptive discharge by taking this between platinum points in a tube of phosphorus, similarly to an experiment of Davy's, but with better means of experimenting. A considerable quantity of phosphuretted hydrogen was given off, amounting, in several experiments, to more than a cubic inch.

(To be continued.)

THE PROGRESS OF DISCOVERY.

NOT only do things mend when they get to the worst, but they sometimes break down when they get to the best. Mediæval philosophers had just demonstrated, with the very perfection of such logic as the schools possessed, that the earth was the centre of the universe, when Copernicus suggested a disagreeable truth, and Galileo came forward with his far-reaching tube to make that truth visible. The new philosophy was stoutly resisted, but it prevailed at last, and the Ptolemaic heavens "passed away." No doubt bows and arrows were wonderfully perfected by the time gunpowder was introduced; and most likely catapults and battering-rams were vastly improved just before the voice of the cannon was heard. Coming down to our own days, how proud we were of our turnpike roads and mail coaches, just when the shriek of the locomotive began to wake up the echoes of our mining districts. Our stage coaches had become elegant, our coachmen and guards were public pets, and the spanking team was the wonder of the villagers and the grand sight of the market town; when suddenly there came in view the roaring locomotive, the terror of the timid, and the detestation of all who loved the road. MacAdam had levelled our highways, and our horses were doing their work splendidly—the world had never seen such vehicles or such charioteers—when the steam cloud came and overshadowed all the glory, till the roads were deserted, the inns shut up, and the coachman compelled to come down from his box. So has it been again and again in the history of human inventions and institutions. The thing is just perfected when it has to be thrown aside. The house is just built when it has to be razed to its foundations. We sit down by the roadside and think our journey is done, when we have to rise up again and renew the race. We perfect some warlike arm, and it is superseded by another. We build a fleet, and forthwith we find it useless. We build again, with the like fate, until at last our dockyards become little else than depôts for old and useless structures. "Out of date" is written upon countless efforts of the human mind, and "Ichabod" could scarcely convey the idea of greater desertion.

The waggon superseded the pack-horse, the coach to a great extent superseded the waggon, the railway has eclipsed them all; and is it possible that something shall outshine the railway? Will the steam horse and the accompanying train ever be looked upon as antiquated and obsolete, like long-bows, matchlocks, and three-deckers? The realisation of such an idea seems impossible. But who thought of steam ships in the days of Nelson, and where was the electric telegraph forty years ago? Locomotives may, indeed, go down to the last days, for all we know; but science is a progressive thing, and the scene perpetually changes as the years roll on. Railways are supreme just now, as stage coaches once were. Opposition has been threatened in the shape of balloons, but the railway share market is insensible to the danger. Perhaps the railway, in some form or other, will be a perpetual institution. It is more easy to conceive this to be the case than the contrary. We can understand that the art of printing may be modified, but we can scarcely apprehend it possible for some new discovery—some hitherto unheard-of invention—to arise and confound the printer's devil by entirely sweeping away the art to which he is apprenticed. So with the railway—it may be modified, yet remain. Some signs of this already appear. Our engineers have of late been applying the principle of the popgun and the air-pump to the transit of certain mail-bags, placed in a suitable carriage on the rails of a tubular subterranean railway. More recently the ingenious individuals connected with the Pneumatic Dispatch Company have become ambitious of conveying passengers in like manner. One or two adventurous beings have even allowed themselves to be shot

through the Post-office tube; but at the present time it is quite possible to test the atmospheric system in a more agreeable and formal manner. Mr. Rammell, the inventor of the pneumatic dispatch scheme, has applied his principle to the propulsion of a full-sized passenger carriage, in a tunnel constructed for the purpose in the grounds of the Crystal Palace Company. Steam power, exercised by a fixed engine, exhausts the air, or forces it into the tube, as may be requisite, and the carriage—attached to a proper disc, and travelling within the tube—is either sucked or blown along, accordingly as it goes one way or the other. Seemingly a very moderate power is sufficient for this purpose, and so far as the mechanical practicability is concerned Mr. Rammell's plan seems to be a great improvement on that which was tried some years ago by Messrs. Clegg & Samuda, on the London and Croydon Railway. Propulsion of this kind is now actually accomplished, steep gradients have been surmounted, sharp curves have been traversed, and curious visitors have personally tested this novel mode of travelling.—*Morning Herald.*

CAPTAIN SELWYN'S METHOD OF LAYING SUBMARINE CABLES.

THE following letter has been addressed to Captain Selwyn by Captain Tribe, a gentleman who has had considerable experience in the submersion and raising of submarine telegraph cables :—

Dear Sir,—I have, with care and interest, read over your pamphlets upon the "Use of Cylinders in laying Submarine Telegraphic Cables in Deep Seas." As I have been engaged with submarine cables for the last few years, and have had some experience in towing at sea, I feel happy in contributing my small share of testimony in favour of an object which, I have every reason to believe, will become of valuable importance. * * * * I have, therefore, no hesitation in giving my cordial support for the adoption of the cylinder to lay telegraph cables, as I really and truly believe that it is *the* method, and the only *honestly safe* method, for laying cables; and this opinion, I feel confident, would be verified if gentlemen interested in submarine telegraphy would but give an experimental trial of the cylinder, by having one made, and on it coiled some old iron-wire rigging, to be paid out in the Bay of Biscay, or off the bank of soundings, at the chops of the Channel. Before concluding these few of many remarks that could be brought to bear upon this subject, I will show the great saving that would result from the use of the cylinder. In a ship—you must have one built for the purpose, or go to the tremendous expense of having her holds fitted for the reception of the cable coils, by removing stanchions and beams, building tanks for the cable to be coiled in for constant testing (and woe betide these when rolling heavily in a gale of wind)—the decks are ruined by being cut up for heavy paying out machinery, the wear and tear of which can only be known by experience (inquire of the officers of the Agamemnon). Then there is the heating of the hold, the chances of damage to cable in coiling and uncoiling, the chances of cable shifting when the vessel rolls heavily, straining her fore and aft, and accidents, whether purely so or malicious. Treble the crew, the wages and provisions; and what with the changes of coils from forward to aft, and gun-deck to orlop, the constant change of watches for the men, and a thousand other incidents too many to be enumerated, but still existing, there is a combination of anxieties which must ever attend the responsible parties entrusted with the paying out a cable from a ship. With the cylinder, the first expense is the only great one; though that is only one-fourth of what a ship would cost; and when once fairly started with the cable, testing satisfactorily from end to end, come fair weather or foul, you have your ship free, your cable on a vessel that will never strain it, nor founder with it; there will be no shifting, no accidents, no fear of too much brake power, and no heart-wearing anxieties that *must* exist when the cable is inside the ship instead of out. I will now conclude, by wishing you heartily every success; and if I am permitted to witness its trial on the broad Atlantic, I feel certain I shall have the pleasure of congratulating you on your triumph; but on the sea, it (the cylinder work) *must* be consigned to your management, assisted by nautical men, and *not* to civil engineers and electricians, who will have quite sufficient to occupy their minds and time in filling their own legitimate spheres.

I remain, my dear Captain Selwyn, very faithfully yours,

THOS. TRIBE.

ANNUAL REPORT BY CHAS. TODD, ESQ., SUPERINTENDENT OF TELEGRAPHS, &c., SOUTH AUSTRALIA, 1863.

Observatory and Telegraph Department, Chief Office, Adelaide, April 6th, 1864.

Sir,—I have the honour to furnish you, for the information of His Excellency the Governor-in-Chief, with the following report on the operations of this department for the year ending 31st December, 1863.

NEW LINES.

The only extensions during the year were from Kadina to Port Wallaroo —rather more than seven miles; opened on March the 23rd; total cost, £416 13s. 7d.; and from Penola to Kincraig, thirty-one miles, costing £1,496 11s. 5d., on the 20th July. A station was also opened at Wellington on the 17th March.

The following statement exhib'ts the amount of business transacted at each of the foregoing stations, and the annual cost of management according to the estimates for the present financial year.

Station.	Cash Receipts.	Paid at other Stations.	Salaries of Officers, per annum.
Wallaroo	£131 16 0	£107 1 6	£175 0 0
Wellington	41 9 3	35 18 6	60 0 0
Kincraig	37 13 9	13 12 6	90 0 0

No station has been built at Wallaroo, but is much required, as I am at present obliged to rent a small wooden building consisting of two rooms of exceedingly limited dimensions, altogether insufficient to accommodate the officer in charge, who should reside on the premises. If a suitable building were erected I believe the postmaster-general would place the post-office under the charge of the station-master. The rapidly increasing trade of the port will soon render this one of our best outstations, and the transactions of the past year afford, in my opinion, but an imperfect criterion of what may be expected when the mineral resources of Yorke's Peninsula are more fully developed.

The station at Kincraig is placed under the charge of the Clerk of the Local Court, Mr. Horsfall, who, until a court house is erected, has to provide the necessary office accommodation. The single needle magnetic instrument is used to work with Penola, where the messages are repeated.

The station at Wellington is principally valuable to the police, to whom it has already rendered important aid. Mr. Carter has had charge of the office since November, an operator having previously been placed there to teach him, and it is only due to state that he has hitherto acquitted himself very creditably; but it will be obvious that his other duties as ferryman call him too much away from the office to allow of his efficiently performing the work of the telegraph.

On the removal of the military from the colony, it was thought desirable to place the comptroller of convicts at the Stockade, in direct telegraphic communication with the Adelaide office, and, in compliance with your instructions, I made arrangements, towards the end of the year, for carrying a special wire to the Stockade, communicating with the Central and Railway telegraph offices in Adelaide. The north line has been re-poled, and an additional wire suspended as far as the Dry Creek, from which point the communication is continued by the wires previously erected along the branch line to the Stockade. To render the system complete, an operator is required at the Stockade, and until one is appointed I fear the line will be practically useless, should its aid be necessary in any outbreak or disturbance among the prisoners.

The extent of lines open in South Australia, at the end of the year, was 747 miles, and 1,064½ miles of wires, connecting thirty-eight stations.

CONDITION OF LINES.

Most of our lines have now been up some years, and hitherto have cost but little for repairs. On the Port line, square Swan River mahogany poles were used, and although they have now been in the ground somewhat more than eight years, most of them are perfectly sound. On the Gawler line, round boxwood saplings from Kangaroo Island were planted; they have been up rather more than seven years, and are rapidly decaying, although I was led to expect great durability. They were, originally, too slight and short to bear more wires, and, in erecting the Stockade wire, I have recently re-poled the line as far as the Dry Creek.

The poles on the intercolonial line are mostly stringy-bark and gum saplings; they have been standing now between six and seven years, and, in some places, are becoming unsafe, and, owing to the extreme severity of last winter, considerable expense was incurred for repairs. I expect to have to re-pole the line, or the greater part of it, during the next three years, a moiety of the cost for which may have to be provided for in the estimates for the ensuing financial year. As we have no serviceable local timber between the ranges on this side of the Murray and Mount Burr, a distance of nearly 200 miles, it is a question whether it would not be better, and in the end cheaper, to use square poles (Swan River mahogany, or gum, &c.) instead of saplings, along the coast and for some miles beyond Guichen Bay. The New Zealand *totara podocarpus* has been very highly spoken of, and is, I understand, very extensively used by the natives in the construction of their "pas" and villages. Some of the logs which have been in the ground for fifty years have been found, it is stated, to be perfectly sound. On the northern lines native pine poles have been used throughout beyond Gawler town, and, at present, are mostly quite sound.

WORKING OF LINES.

With the exception of two serious interruptions on the intercolonial line in August and September last, the whole of the lines have worked satisfactorily. I have given in this report a detailed statement, showing every interruption, with its duration and locality, which occurred during the year, from which it appears that on the main line the communication has been wholly or partially suspended as follows.—

On the north lines, there were fifteen (15) interruptions, of which nine (9) were attributable to defects or inadvertence in the stations, causing stoppages varying from one and a-half (1½) to five and a-half (5½) hours, and amounting, in the aggregate, to twenty-five and a-half (25½) hours; one (1) of eight (8) hours to severe thunder storms; and four (4) to accidents on the line, one of which, caused by a bush fire, cut off the Kadina and Wallaroo offices for one and a-half (1½) days; the other three caused interruptions varying from two (2) to eight (8) hours, amounting in all to sixteen (16) hours.

On the South-eastern, No. 1 line, worked as far as Goolwa during the

greater part of the year, there were ten (10) interruptions, no less than seven (7) of which were caused at stations, amounting to three and a-half (3½) days and twelve (12) hours; and three (3) of thirteen (13) hours, in the aggregate, by accident on the line.

On the South-eastern, No. 2 line, which formed the main intercolonial line throughout the year, there were seven (7) interruptions, four (4) of which originated in offices, and three (3) on the lines. Of these, six (6) cut off our communication with Victoria; on one occasion for six (6) days, from July 30 to August 4, by the breaking of the wire in the swamps between Guichen Bay and Mount Gambier, and on another for four and a-half (4½) days, through a defect in the wires leading into the Guichen Bay office, which the station-master unfortunately failed to discover until after the whole of the line between Guichen Bay and McGrath's Flat had been carefully inspected. The other three stoppages on the intercolonial line were trifling, amounting in the aggregate to 15 or 16 working hours; although, owing to the severity of the winter season, the line occasionally worked badly in the months of July, August, and part of September.

If we take into consideration the nature of the country traversed, and the exposed positions of the lines to all sorts of injury, and the difficulty in some cases of promptly effecting the repairs, especially where the line crosses, as in the South-eastern district, extensive swamps, in many places, last winter, three or four feet under water for many miles, it will, I think, be admitted that the interruptions are much fewer, and of shorter duration than could be expected. Persons give us credit for many delays which never occurred; for instance, it is very commonly reported, especially in Melbourne, that the line is rarely in working order when the English mail arrives, while the contrary is really the case; the line is seldom interrupted at mail times, and, not unfrequently, the English news has been so promptly transmitted to Melbourne, as to place the public there in possession of the intelligence before it has become generally known in Adelaide.

To prove this I have prepared the following statement, showing the rate at which mail messages have been transmitted during the last two years, 1862 and 1863.

Table showing the rate at which Mail Reports were transmitted from Adelaide to Mount Gambier during the years 1862 *and* 1863.

Date of arrival at Glenelg.	Average rate of transmission; number of words per hour, including stoppages.	Remarks.
1862.		
January 11, 1.30 p.m.	1,600 words	Reports reached Adelaide at 2.35. The first report of 1,788 words finished at 3.45.
February........	—	No mail.
March 11	1,400 words	Commenced at once. First report of 2,148 words finished at 1.20 a.m. of March 12.
April 15, 3.30 a.m. ...	1,400 "	All the reports finished at 7 a.m.
May 9, 7.30 a.m. ...	1,100 "	All the reports finished at 12.50 p.m.
June 9, 11 p.m.	1,200 "	Maximum rate of transmission, 1,500 an hour. All finished at 2 a.m. of 10th.
July .... August........ September	—	No mails.
October 7, 12 noon ..	1,350 words	All finished at 4.35 p.m.
November 10, 5 a.m. .	1,100 "	First report finished at 7 a.m.; all at 9.15 a.m.
December 12, 1 a.m. .	1,450 "	All finished at 4.18 a.m.
1863.		
January 12, 5.35 a.m..	1,100 words	First report finished at 6.50 a.m.; all at 10.30.
February 12, 1.41 p.m.	1,100 "	Maximum rate, 1,500. All finished at 4.45 a.m. on 13th.
March 17, 5.43 p.m...	550 "	Line working badly; heavy rain throughout. Last report sent at the rate of 840 words an hour; all finished at 3.25 a.m. on 18th.
April 12, 9.5 p.m. (Sunday)	1,050 "	First report of 2,365 words received at 10.30 a.m.; finished at 12.45.
May 11.........	—	Steamer brought no mail.
June 14, 1 p.m. (Sunday)	1,350 words	The first report of 2,725 words was sent in two hours, and over 9,000 words under eight hours.
July 11, 8 a.m.	1,400 "	The first report of 2,425 words commenced at 9.20, & finished at 11.5.
August 9, 8.18 p.m..	1,100 "	All finished at 3 a.m. on 10th.
September 8, 10 p.m..	—	Line interrupted. [*Vide* table of interruptions.]
October 8, 6 p.m. ...	1,250 words	All finished at 10.50 p.m.
November 12, 4.35 p.m.	1,275 "	Finished at 8.25 p.m.
Dec. 13, 11.15 a.m. ..	361 to 600 words	Reached Adelaide at 1; commenced at 2 p.m.; line interrupted for about five hours after reports were commenced. The last half of the reports transmitted at the rate of 600 words an hour. Furious gales, with drenching rain and lightning along the whole line.

From the foregoing, it appears, therefore, that so far from the telegraph invariably failing on the arrival of the mail, it has done so only once during the past two years. On several occasions last year, which was remarkable for its atmospheric disturbances, we had exceedingly unfavourable weather just as the mail came in. In March, for instance, we had heavy rain along the whole of the South Australian line, and similar weather in Victoria; but, although the messages were transmitted with considerable difficulty, the great bulk of them were sent, after a little delay, direct to Mount Gambier, a distance of 300 miles.

It will be remembered by every one that, on the arrival of the mail in December last, a furious gale, with heavy driving showers, preceded by severe thunderstorms, swept across the whole of our coast lines. The mail arrived on Sunday at one (1) p.m., and was immediately notified to Melbourne, and, despite the increasing severity of the weather, the despatches, after a few hours' delay, were transmitted over a circuit of 300 miles at nearly the ordinary rate.

When the extension of the telegraph was first proposed, our oldest colonists predicted that it would be constantly liable to interruption. Now, however, although when it is put to them, persons will acknowledge that it is, after all, more surprising that the interruptions are so few, than that they are so frequent; they are, nevertheless, very apt to exaggerate the failures and impute negligence whenever they themselves experience any personal inconvenience. And one stoppage on the arrival of the mail causes so much disappointment, that one can readily understand how it should leave a deeper impression on the memory than a dozen successful operations.

As an instance of the disposition shown by some to attribute every delay to defects or obstructions on the line, I may cite the following .—On the arrival of the English mail in February, the only despatches landed at Glenelg were those addressed to the Melbourne *Argus*, and *Sydney Morning Herald*, with a few private telegrams under the same cover. These reached the Adelaide office at 6.45 p.m., and were immediately transmitted direct to Melbourne (without repeating), over a circuit of 700 miles, at the rate of about 1,200 words an hour, including all stoppages. On their completion, the line was wholly unoccupied for nearly three (3) hours, the rest of the despatches not having arrived from the port. This was explained by the manager in the Melbourne office, and it must have been known, therefore, that the line was waiting; the *Melbourne Herald*, nevertheless, attributed the delay to the South Australian Telegraph.

It is right to mention that the *Argus* acknowledged the early transmission of the first report, and neither that paper nor the *Sydney Morning Herald* has complained of telegraphic delays for some time past.

I regret to have to report frequent and extensive damage to our lines, especially where they pass through country townships, by mischievous persons throwing stones at the insulators. Much of our difficulty in bad weather arises from this cause. With a view of preventing it, I propose affixing a notice on the poles offering a reward for the apprehension of any offender. We had nearly 100 insulators broken, between Adelaide and Mount Barker, in a few days at Christmas.

Mistakes in Telegrams.

The errors of the telegraph have become a proverb in all parts of the world where it exists, and it would be worse than useless for me to attempt to combat the almost universal opinion. Nor will I set up a claim on behalf of my own department for more than ordinary accuracy. Another time I hope to be able to place before you some reliable statistics as to the number of errors, for it is my intention in future to have a record kept of every mistake of which complaint is made. I will here content myself with referring to the errors which came to my own knowledge during the past year, and offer a few suggestions which, if adopted, would, I think, tend very considerably to diminish the number and importance of telegraphic blunders.

It may be safely assumed that no important errors or delays, involving pecuniary loss or serious inconvenience, occur which do not come before me. Now, out of the 86,411 messages which passed through our offices during the year, I have a record in my letter-book of sixteen (16) being referred to me containing mistakes; and, as far as my memory serves me, scarcely as many more came under my notice, which were replied to verbally.

I shall be quite safe in saying that not more than thirty-six (36) messages were referred personally to me, as erroneous. Two of these were mistakes on the part of the sender, in addressing the message to the wrong firm; one was the omission of a full stop, and as it is instructive, and will at this time be no breach of faith, I will give it. The original message read thus:—"Butter sold returns as last. Send more. Flour thirteen ten (£13 10s.)" It was sent thus:—Butter sold returns as last. Send more flour thirteen ten (£13 10s.)" And I believe more flour, instead of more butter, was sent to Melbourne.

The errors referred to me would be those of the greatest importance. On reference to the cashier in the Adelaide Office, through whose hands at least 60,000 messages passed in the last twelve months, I find that on the average one message in three days is referred back to the office for explanation. It is not, of course, pretended that only one hundred (100) errors were made; but what I have stated serves to show, that out of some 60,000 messages not many more than 100 contained errors of sufficient gravity to require their being sent back for explanation.

This, I think, is very creditable to the department; for it must be remembered that every message has to run the chance first of being sent

incorrectly by the transmitting operator, who at a busy instrument has often no opportunity of previously reading the messages he transmits, which, by-the-bye, are frequently badly written, and secondly, of being wrongly rendered by the receiving clerk, who writes it at the dictation of the instrument, the utterances of which are affected by the state of the weather, &c.

Many errors occur in the rendering of words having a similarity of sound, such as "to" for "two;" "for" for "four," &c.; and from the code signals of two different words closely resembling each other unless sent carefully; for example, in one instance the word tons (— ——— —· ···) was substituted for kegs (—·— · ——· ···), the operator transmitting the word thus (—·—·——·—·····). "Meet" (—— · · —) is liable to be read "get" (——· · —).

The most singular error I have met with was in a message in which the sender telegraphed for the "coil of belting;" it was written very indistinctly, and the operator transmitted it, "Send the evil of betting." One can imagine the perplexity of the receiver.

The most serious errors occur in quotations, and might be easily avoided if persons would repeat them in a different form, so as to enable the receiver to verify the correctness of the telegram; thus, "Wheat five and six—sixty-six." "Flour eighteen ten—three seventy;" "one thousand—twice five hundred," and so on. There is some little art in writing a telegram properly; persons should always avoid writing a message so that its sense may be reversed or wholly altered by the omission of a single word. "Not," for instance, is a very dangerous word where the sense of a message wholly depends upon it.

Questions as to the authenticity of bank credit telegrams have at times been raised; the difficulty in the majority of cases might perhaps be met somewhat in the following way: suppose the manager of a bank in Melbourne to have frequent occasion to telegraph to the manager in Adelaide, who it is desirable should be able to determine the genuineness of each telegram, let the former select a number of words—"Jericho," "Jordan," "Jerusalem," &c., and send a list to the Adelaide manager; and afterwards let each message commence with one of the words fixed on, taking them in consecutive order; the first beginning "Jericho," and so on. If this were adopted, it would be quite impossible for any fraud to be committed, for no one could discover the "key." Letters would not be so good as words, as the operator would be more liable to mistake them.

There is no doubt that important messages should be repeated; but the public complain of the extra expense; and I think the charge for repeating might with advantage be considerably reduced for the higher rate messages.

It is, of course, our duty to guard against mistakes in every possible way, and to adopt every possible precaution which circumstances permit; and this is done. It has been suggested that a system of fines would act beneficially, by inducing greater care on the part of operators, and perhaps it might. Unfortunately, however, the system would press unfairly on our best operators, who, as such, are placed at the instruments which do the most business; and, as it would be unreasonable to expect that the number of errors would—the operators being equal—vary with the number of messages, that operator who had most to do would make the greater number of mistakes. Indeed, the one who had less to do, and therefore more time to be careful, should, from that very circumstance, make proportionally much fewer errors. Thus it will be seen that, while one operator at a busy station will with every care be certain to make mistakes, through the pressure of business, another operator, who may perhaps be really less careful and painstaking, yet having less to do and more time to do it in, will be, from that circumstance, more exempt from errors. It is better in practice to treat each case on its own merits; and if an operator is found to be habitually careless, the superintendent should have the power of summarily dismissing him.

(To be continued.)

TELEGRAPHIC NEWS.

Another Transatlantic Telegraph.—*On dit* that a Company has been formed in Spain, with a large capital, for the purpose of carrying a novel telegraph cable across the Atlantic by a new route.

Electric Induction.—At the meeting of the British Association, now being held at Bath, J. B. Thompson, Esq. will read a paper on "The Mechanical Theory and Application of the Laws of Magnetic Induction." We hope to be able to lay this valuable contribution to scientific literature before our readers next week.

Telegraph Improvements.—The sporting papers of the week announce that at Doncaster race-course, the wooden sheds of the Magnetic and Electric Telegraph Companies have been replaced by permanent offices, whilst the unsightly telegraph posts have disappeared, and the wires are carried underground.

The Velocity of Electricity and the duration of the spark have been made the subject of experiment with new apparatus by M. Felici, of Pisa, and described in the *Cimento.* He has determined the velocity to be 260,000 kilometres per second. The following are the determinations of other philosophers:—Wheatstone, 480,000 kilometres; Fizeau and Gounelle, 180,000; the astronomers of London and Edinburgh, 12,200; those of Brussels, 4,300. The kilometre is 0·6213 mile.

The Indo-European Telegraph.—We are glad to be able to announce that the convention between the Ottoman Government and the Government of India for the Indo-European telegraph, viâ Bagdad and the Persian Gulf, was signed on Saturday last, the 3rd of September, by the respective plenipotentiaries of the British and Turkish Governments.—*Levant Herald.*

Atlantic Telegraph Company.—The following circular has been sent to all the shareholders and others interested in the above undertaking:—"Atlantic Telegraph Company.—Notice of Removal from 22, Old Broad Street.—The offices of the Atlantic Telegraph Company are now removed to No. 12, St. Helen's Place, Bishopsgate Within, E.C., to which place all communications are in future to be addressed.—George Saward, Secretary and General Superintendent.—12, St. Helen's Place, Bishopsgate Street, September, 1864."

Interruption of Telegraphic Communication between Benghazi and Alexandria.—We regret to state that an interruption of communication on the cable between Benghazi and Alexandria occurred on the 6th September. The position of the break is said to be from 180 to 200 miles from Benghasi. The screw steamer Fanny Lambert, which has been lying some time in the Malta Harbour and is fitted with the necessary apparatus for lifting up the cable, left on the 8th, having on board Messrs. Temple, Saunders, Gibbs, Windle, Fryer, Joss, Smith, Bence, Horne, Stephens, Bacon, Jarman, Hough, Hoskins, Marshal, and M'Combie, of the telegraph staff, for the purpose of repairing the faulty part, and will be assisted by her Majesty's screw steam corvette Racer, to follow as soon as a telegraph official expected from England arrives.

The Otrante and Avlona Cable has been satisfactorily completed. The previous attempt to submerge this cable in the month of February last proved unsuccessful on account of severe gales having been encountered which drove the vessel out of her course, whereby the end of the cable was lost. The repairing expedition, under the personal superintendence of the contractor, Mr. W. T. Henley, has succeeded in picking up the end from a depth of 569 fathoms (the greatest depth from which any submarine cable has been recovered). The completion of this line will bring Constantinople into more direct communication with London than before.

Electric Clocks.—Last month a large electric clock was put up in front of the Main Guard, on St. George's-square, Malta. This time-piece has a dial two feet in diameter, and is placed in a lantern. It is visible from the Palace, works with great regularity, and has a very striking effect when lit up by gas at night. Stoppages are not likely to occur when everything is properly regulated and systematized, and a proper amount of motive power, as well as duplicates of it, for exchanging exhausted batteries, are at the disposal of Mr. Rosenbusch, to whom great praise is due for his zeal and disinterestedness in promoting the adoption of this useful and novel timekeeper.

New Zealand.—The military electric telegraph is not to stop at Ngaruawahia, but is to be extended to all the outlying posts and down to Raglan, on the west, and Tauranga, on the east coast. The material for this is now on its way here, and a staff of engineers left Auckland on Friday, 13th May, to make the necessary preparations. When the material comes to hand the work will not be long in execution, and we may expect, before many months, to be in telegraphic communication with the principal military posts throughout the island. We would suggest to the Provincial Government that a single wire to Onehunga could be put up and worked at a comparatively small cost, and that with vessels arriving there so frequently as they do now, it would be a great public convenience.—*Southern Cross.*

New South Wales.—A deputation of gentlemen, representing the coal mining property at Lake Macquarie, waited on the Minister for Works with a view to certain improvements being effected in the navigation of the entrance of the lake. The minister promised to give his immediate attention to the matter, the improvements sought being estimated at above £3,500. Several new private buildings are begun, and many alterations of premises in various parts of the city are in progress. The Episcopalian church at Binda is finished, a neat and substantial edifice of rubble stone. It will be seen in another part of our summary how severely we have been again afflicted with floods; and such a calamity has not only injured many Government works, but considerably damaged private property. For repairs towards bridges, railways, harbours, electric telegraph posts, jetties, and other public property, the Minister for Works will have to submit to the next session of Parliament a considerable item on the supplementary estimates.—*Empire.*

The Telegraph to America.—Adverting to the Atlantic telegraph, the *Morning Herald* observes:—"One of the most serious difficulties with which those engaged in laying telegraph cables have to contend arises from the risk of snapping or straining the cable when paying it out over the stern of the ship. In calm weather the "paying out" is comparatively easy; but when the sea is rough, and the vessel rises and falls with the motion of gigantic waves, the probabilities of severing the cable are increased to such a degree as to render the task well nigh impossible. Experience, however, has made telegraphic engineers fertile in contrivances, and an apparatus has been constructed to regulate the rate of discharge of the cable from the Great Eastern, which it is believed will compensate for the unequal strain which would otherwise be created by the violent motion of the vessel in a heavy sea. It is not known to what cause the failure of the first cable is to be attributed. The insulation of the wires was destroyed; but whether from the effects of a strain in laying the cable, or from an injury sustained

by the latter by coming in contact with some sharp submarine reef, or, as some conjectured, from the effects of the superincumbent weight of the ocean, was never discovered. In the construction of the present cable, which is considerably larger and stronger than the previous one, great pains have been taken to guard against the known as well as the suspected dangers of the hidden depths of the ocean, and the projectors are confident that, if once securely laid across the Atlantic, telegraphic communication will henceforth continue uninterrupted between the continents of Europe and America. The civilized world has now become so habituated to telegraphic intelligence, that any break in the chain of communication between different parts of the globe is regarded as a misfortune which is positively intolerable. The time was—and not very long since either—when we considered we had achieved much in obtaining intelligence of what passed in New York or Washington in less than a fortnight after its occurrence. But the triumphs of electricity have, so far as regards the transmission of tidings, thrown those of steam into the shade. When we find on our breakfast-table each morning short abstracts of the chief events which have taken place during the preceding twenty-four hours in every capital in Europe, we cannot refrain from a feeling of disappointment on reflecting that we will have to wait at least ten days to learn the simultaneous occurrences at the other side of the Atlantic. And there certainly are occasions on which this thirst for early news is not the mere offspring of pampered curiosity. At the time when the outrage on the passengers in the Trent was committed, telegraphic communication between this country and America would not merely have served to allay much anxiety, but would have been the means of saving this country a large expenditure of money. We were compelled to transmit instructions in the ordinary way to our ambassador, and, meantime, to guard against a possible refusal by the American Government to comply with our demands, we were forced to despatch troops to Canada. Had telegraphic communication been possible at that time our wishes would have been made known, and the subsequent concession of the American Government been granted, within less time than was necessary to prepare for the transportation of the troops which were sent to defend our American colonies in the event of a war."

CAUTION AGAINST INTERFERENCE WITH THE TELEGRAPH.—A copy of the following circular has been forwarded to every station agent and telegraphist employed on the London and South-Western Railway :—"On the 9th August, George Thomas Scott, whose father is a porter employed at Gillingham Station, was summoned before the magistrates sitting in petty sessions at Shaftesbury, on a charge of interrupting the transmission of various messages passing through the instrument. Three cases were gone into, but the boy being only thirteen years of age, the magistrates were disposed to deal leniently with him, and discharged him with a caution, considering the blame to rest primarily with those who, being in charge, allowed the telegraph to be exposed to such irregularities. Undoubtedly the persons chiefly to blame were the station agent and telegraphist at Gillingham; and all concerned should be aware that in any future case of the kind the law will be found to apply as well to those who, by their negligence, conduce to interruptions as to the actual perpetrator.—W. H. PREECE, ARCHD. SCOTT.—Telegraph Department, Southampton Station, 25th of August, 1864."

MISCELLANEA.

FIRST USE OF PENS.—A writer in the *British Quarterly Review* tells us that Queen Jezabel is the first letter writer on record, and that she used her pen for purposes of deception.

ACUTE OBSERVATION OF THE EFFECTS OF CRINOLINE ON THE MAGNETIC NEEDLE.—A Kingston (Canada) paper speaks of the smoke from the fires which prevail around the country as impeding navigation on the river St. Lawrence; and the other day, in the case of a pleasure party on a steamboat, while the smoke was so dense as to require the use of the compass, there were so many fair passengers with steel hoops that the compass became entirely unreliable, and the boat finally brought up at Portsmouth instead of Kingston!

THE NEW ZEALAND EXHIBITION.—Papers are now being distributed detailing the various regulations under which articles will be received for and exhibited at this Exhibition, to be opened in the city of Dunedin on the first Tuesday in January, 1865. The articles exhibited will be divided into classes or sections, consisting of raw materials, machinery, manufactures, and fine arts. The Commissioners will receive articles on or after the 1st of October next, and will continue to receive goods until the 12th December in the present year. Application for space and other information is directed to be made to Mr. John Morrison, New Zealand Government Agency, 3, Adelaide-place, King William-street, London, E.C.

ALUMINIUM.—A new method for obtaining this metal at a very small cost has just been discovered, says *Galignani*, by M. Corbelli. He takes a certain quantity of fine clay, say 100 grammes, and dissolves it in six times its weight of concentrated sulphuric, nitric, or hydrochloric acid. The solution is then allowed to stand, and is afterwards decanted. The residue is first dried and then heated to 450° or 500° centigrade; after which it is mixed with 200 grammes of prussiate of potash, which may be increased or diminished according to the quantity of silica contained in the clay. To this mixture 150 grammes of common salt are added. The whole is then put into a crucible and heated until the mixture becomes white; when cool, a button of pure alminium is found at the bottom of the crucible.

ARRIVAL OF THE MAIL IN MELBOURNE.—A writer in *Chambers' Journal* makes the following observations concerning the reception of news from Europe and its transmission from Adelaide to the inland towns :—"About the 5th of every month the telegraph authorities in Melbourne make their first preparations for the reception of the summary of English news. One of the clerks in the office, called an operator, has to sleep all night in the office, with a bell over his head, which is rung by electricity. This arrangement is a very necessary one, as the arrival of the mail is sometimes telegraphed in the middle of the night. The mail telegraphic correspondence, in nine cases out of ten is first carried on between Adelaide, the capital of South Australia, and Melbourne, the capital of Victoria. It is at Adelaide that the mail steamer arrives first, and that town consequently is the first to get the European news and the first to transmit it."

THE INFLUENCE OF LIGHT ON THE RETINA.—All the senses are more or less subject to deception; but the eye is pre-eminently so; especially when the sensibility of the retina, and also the imagination, are unduly excited by disease. If we fix the eyes upon a highly illuminated object for a few seconds, and then look toward a clear wall, or the sky—the mind being unattracted by other things—we will see an exact figure of that object; this illusion will gradually grow fainter until it vanishes entirely. We are thus naturally led to the conclusion that the impression of light on the retina of the eye is not merely instantaneous, but that it actually continues during a certain time after the luminous or illuminated object has been withdrawn.

CURIOUS EFFECT OF LIGHTNING.—The *Journal de Loiret* relates the following curious fact on the authority of M. Lebigue, Mayor of Nivelle :—"As three men were gathering pears on Sunday last in that commune, the lightning struck the tree, and passing down it in a spiral line, stripped off a piece of bark from top to bottom, about half an inch thick and four inches wide. One of the men, who happened to be eating his breakfast near the foot of the tree was killed on the spot, as was also a dog standing near him. The other two men, who were in the tree when the lightning flashed, were knocked down by the shock, and remained for some time insensible. On reviving they found their legs in a measure paralysed, but recovered the use of them before evening. On examining one of the men an impression of the branches and foliage of the pear tree was found distinctly printed on his breast—a phenomenon of which many instances are recorded."

THE PROGRESS OF CIVILIZATION.—The Maories at Waikato Heads, we are told, are becoming patrons of the Savings' Bank, and there has been a considerable sum lodged by them. It is an important change in their habits, that of the appreciation of the system of increase in money by interest, instead of the desire to hord specie in their whares. It destroys the spirit of communism which has hitherto prevailed amongst them and which induced them to share any money each might have gained. The desire of individualising property once established amongst them, they will settle down and attend to their own interests without being swayed by every barbarous caprice of a tribe. It will also be an additional tie to civilisation, and the thought of money invested with the pakehas will counteract any desire to quarrel with them. Another improvement is the establishment of co-operative stores, by which a gang of Maories engaged on any undertaking, such as a surveying party, may obtain their goods by wholesale and supply one another with every man's share, keeping an account of how much each is entitled to.—*New Zealander.*

MAGNESIUM.—A correspondent of *Notes and Queries* has forwarded to that interesting publication a paragraph which originally appeared in this journal, and thereto has appended the following remarks :—"I have purchased a few feet of the wire, and find the statement correct—a more brilliant and beautiful light it would be difficult to imagine; and I suppose it will not be long ere many uses are found for it in the arts of peace and war. I have also seen some *cartes de visite* of Sir Henry Holland, Professors Faraday and Roscoe, and others, taken by its light; and, unless assured of the fact, could not have distinguished them from first-rate sun portraits. Probably photographers will now commence to work by night as well as by day, and relieve their stout and elderly customers from tiresome ascents to studios on the roofs of houses. Magnesium, I learn, is at present extracted from magnesia at works in Salford, Manchester, under the superintendence of Mr. Sonstadt, who, notwithstanding his name, is an Englishman, but of Swedish descent.—HARDIE CLARKE."

EXPLORATIONS IN NORTH WEST AUSTRALIA.—THE DISTRICT OF THE GLENELG.—In the division of the indigenous vegetable productions little can be safely predicated until opportunity has been afforded for an investigation into the medicinal properties of the plants already discovered, which doubtless form a very inconsiderable number of this class within even the limited area explored. The abrus and the anatherum, the pea, and the lemon grass, as of most frequent occurrence, may be considered first: from the roots of the former we expect a perfect substitute for liquorice in every respect; from an infusion of the leaves of the latter we know, from Indian experience, we can obtain a tea acknowledged to be stomachic, tonic, and useful in dyspepsia. From the convolvulaceæ, one species of which is included in the genus ipomœa, we may extract deoretin, affirmed to be identical with jalapin; from a second species of the genus convolvulus, scammony or a canthartic resin of equal value may be prepared from the expressed juice of its roots and stalks. From the root stocks of the typha extracts astringent and diuretic are obtainable. An elastic gum, something like India-rubber, and gum tragacynth have been found. Sandaric resin can be procured from the pine, and gum resin of various descriptions from several of the eucalypti.

Electrical Phenomenon.—On Saturday, the 10th instant, between four and five o'clock, a thunderstorm of unusual violence passed over Cheadle and the district, creating considerable alarm. In one instance the electric fluid struck the residence of Joseph Alcock, Esq., of The Croft, near the town, passing through the roof into a room used as a lumber-room, where it set on fire some bags containing feathers and also some loose strips of wood. The housemaid, Susan Bailey, who was in her bedroom on the opposite side of the passage, received a shock which nearly threw her down. On recovering she went into the lumber-room, and, with great presence of mind, took some water and put the fire out. From the latter room the electricity passed through a wooden partition along a bell-wire leading to the drawing-room below, where it shivered to pieces the glass in a picture-frame, while several panes in the window were blown out. Mr. and Mrs. Alcock, who were sitting in the dining-room, received a shock, the latter severely, the former but slightly. In a bedroom over the dining-room the paper was torn up in one corner, but no other marks were to be seen to indicate the passage of the subtle visitor. Had this phenomenon occurred in the night the consequences might have been fatal to the occupants of the building.

The Conductors of Sound.—The air is one medium by which sound is conveyed. But solid bodies convey sounds much better than the air; this fact you may readily prove by placing your ear flat and close upon the end of a long table or a marble chimney-piece, and asking another person to scratch or rap gently with a pin or other body at the other extremity. It is very curious to note how you can thus appreciate the sound produced by the most delicate impulse. Now lift your ear from the table and raise it only two inches, and you can with difficulty distinguish the slightest sound. Solid bodies then are better conductors of sounds than the air; and moreover they convey them with a far greater velocity, as has been proved by the following curious experiment:—"A metallic wire 600 feet long was stretched horizontally, and at one end a plate of sonorous metal was attached; when the plate was slightly struck, a person at the opposite end, holding the wire in his teeth, heard at every blow two distinct sounds, the first transmitted almost simultaneously by the metal, the other arriving later through the air." . . . . But sound is also communicated by liquids: water is an admirable conductor of sound, and though not so good a one as hard and elastic bodies, it is far superior to air. If you have any doubt of this fact let me recommend you to dive down into some pond or river, and take two stones or pebbles from the bottom and knock them together several times in succession. How loud the sound seems! Now come to the surface, and after taking breath take a couple of quoits down with you, and strike them together close to your ear. Why, the noise is almost deafening; and you are satisfied that water is an excellent conductor of sound. Now let me ask you to try the effect of sound proceeding from the rarer medium of air into the denser one of water. Ask your friend on the river bank to strike these same quoits together, while you are under the water. "Did you hear anything?" "Not a sound of any kind," you will reply. Ask him to halloo and shout with all his might. "Could you distinguish any noise?" "I thought I could just recognise a feeble and confused sound as if it proceeded from a great distance." "Perhaps so—but your head was not more than three or four feet beneath the surface; if you will sink down a few feet deeper, you will not hear the slightest indication of a sound."

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2182. W. J. Curtis, improvements in railway carriages and in the means to be employed by passengers in signalling to the guard of railway trains.

2216. M. Fitzgerald and J. S. Phené, protection of the lives and persons of travellers on railways by improved signal communication between any passenger and the guard and other passengers.

2217. H. W. Cook, improvements in electric telegraphs.—A communication.

2218. A. A. Davis, improvements in apparatus for communicating or signalling between the guard and driver, and between the passengers and guard or driver of railway trains.

2228. A. G. Grant, a clock-work magnesium lamp, with reflectors, magnifiers, and condensers, for the burning of magnesium wire to produce powerful light.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2038. W. Milligan, for the invention of an apparatus for communicating motion from one railway carriage to another in a train, applicable for signalling between passengers, guard, and driver, fastening and unfastening the carriage doors, working the breaks, and other purposes.

2049. W. Clark, improvements in apparatus for transmitting motion and power from one part of a railway train to another, for the purpose of effecting communication between the passengers and guard, or otherwise, and for operating the breaks.—A communication.

2052. C. Cotton, improvements in railway carriages, to facilitate the communication of passengers from carriage to carriage of a railway train.

2053. W. Thomas, improvements in effecting communication between passengers and guard or other person in charge of railway trains.

2063. J. Thomsen, improvements in batteries for generating electricity, and in apparatus for converting the quantity thereof into intensity.

2078. T. H. Cleveland, improvements in means or apparatus for signalling between passengers and guards or other persons in charge of railway trains.

2080. R. A. Brooman, improvements in machinery for winding, unwinding, and paying out telegraph cables, applicable also to winding and unwinding cords, ropes, and wires.—A communication.

2123. R. A. Brooman, improvements in signalling apparatus, specially applicable to signalling on board ship.—A communication.

2134. G. Witson, improved means of communicating between passengers, and between passengers and guards, on railways.

2141. Sir J. Mackneill, improvements in railway signals.

PATENT SEALED.

661. E. F. Ruffin, improvements in marine and land signals.

PATENT WHICH HAS BECOME VOID.

2174. C. Pemberton, improvements in railway, ship, and other signals.

NOTICES TO PROCEED.

1126. W. T. Henley, improvements in telegraph wires and cables, and in apparatus used in their manufacture, parts of which improvements are applicable to other useful purposes.

1234. A. Reid, improvements in apparatus used for testing the insulation of electric telegraph wires or conductors.

2064. G. Davies, improvements in submarine shells or torpedoes, and in apparatus for operating the same.—A communication.

TO CORRESPONDENTS.

E. Walsh wishes to know if it is likely that electricity or the galvanic battery will supply a motive power equal and economical as steam at present gives?—Several efforts have been made by Professor Joule, Mr. Allan, Mr. Baynes Thompson, and others, to construct electro-magnetic engines. The great expense of battery power has hitherto delayed the adoption of the electro-magnetic engine for practical purposes; nevertheless, we do not despair of ultimate success in rendering the machine one of real utility.

We have arranged for securing a lengthened report of the proceedings of the British Association now being held at Bath.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

THE TELEGRAPH IN SOUTH AUSTRALIA.

THE report of the superintendent of telegraphs in South Australia, for the year 1863, has just reached us, and, with an appendix, contains some very valuable information. At the close of the year the means of telegraphic communication in this colony extended over an area of 747 miles. The telegraph consists of 1,064½ miles of wire, connecting thirty-eight stations. (Thirty-eight miles of additional wire have been opened for traffic since the date of the last report, and are included in the above estimate.) The cost of maintenance has hitherto been very trifling, but, owing to the heavy gales and long-continued rains of last season, the item for repairs is unusually heavy. It will be interesting to our readers to learn that the Morse instrument (read by sound) is used on the main lines, and that Henley's magnetic single-needle telegraph is employed for the railway service and for branch lines. These are found to work efficiently.

In reply to several complaints made by uninformed persons relative to delay in the transmission of intelligence, the superintendent of telegraphs furnishes statistics of the time in which mail messages are forwarded; and, certainly, the rate of sending and receiving is equal to some of the best performances on European lines. In the ordinary course of business occasional errors of omission or commission are comparatively unavoidable. It is very necessary that some plan should be adopted, whereby the public may be guaranteed the greatest possible accuracy, as mistakes are likely to lead to serious mischief. The Electric and International, the Magnetic, the Submarine, and United Kingdom Telegraph Companies, in seeking this end, have been led to the practice of levying fines for errors, which has, for several years, been a source of annoyance to the most skilled operators on our English lines. Mr. Todd appears to be aware of this fact, and observes, "It has been suggested that a system of fines would act beneficially, by inducing greater care on the part of the manipulators, and so it might. Unfortunately, however, the system would press unfairly on our best operators, who, as such, are placed at the instruments which do the most business; and, as it would be unreasonable to expect that the number of errors would—the operators being equal—vary with the number of messages, that operator who had most to do would make the greater number of mistakes. Indeed, the one who had less to do, and therefore more time to be careful, should, from that very circumstance, make proportionally much fewer errors. Thus it will be seen that, while one operator at a busy station will, with care, be certain to make mistakes, through the pressure of business, another operator, who may perhaps be really less careful and painstaking, yet having less to do and more time to do it in, will be, from that circumstance, more exempt from errors. It is better in practice to treat each case on its own merits; and if an operator is found to be habitually careless, the superintendent should have the power of summarily dismissing him." Were the vexatious system of fining for errors entirely abolished, and were premiums offered for accuracy and expedition in the transmission of messages, every practicable precaution would be observed by operators in their manipulation of the various instruments.

But to return to the colonies. Several important extensions of the telegraph are recommended in the aforesaid report; but it would seem that, until the governments of the various colonies agree upon the proportion in which the anticipated receipts are to be divided, very little progress will be made. In New South Wales, arrangements are pending for a line from Deniliquin to the South Australian frontier. On the Victorian line it is proposed to erect a second wire, to connect Hexham to Hamilton, and thus establish an inland communication between Melbourne and Portland. Both these important works are in abeyance, for the reason before stated.

The financial condition of this colonial telegraph is not so satisfactory as we could wish. The number of messages has increased, and the receipts for the same have been proportionally augmented since 1862, yet the expenditure exceeds the income. It appears that the number of telegrams increased from 76,725 in 1862, to 86,411 in 1863; and the revenue from £7,677 5*s*. 8*d*. in the former year, to £8,429 19*s*. 1*d*. in the latter. The total value of messages in each year was respectively £11,801 3*s*. 7*d*. and £13,120 16*s*. 7*d*., being an increase of £1,319 13*s*. The expenditure, exclusive of the outlay for new lines, was £9,968 18*s*. 10*d*. Of this amount, £8,798 0*s*. 1*d*. was the proportion charged to the working expenses or maintenance account; or, adding the rent of the chief office (£310), £9,108 0*s*. 1*d*., a sum exceeding the net revenue by £678 1*s*. 7*d*., a fact to be accounted for by the circumstance that eleven out of thirty-eight stations are not yet self-supporting.

In estimating the value of the telegraph in a new country it is necessary to consider its collateral as well as its immediate advantages. We regret that, after four years' operations, the South Australian lines should be found to be unremunerative; but it must be conceded that the aid they afford to commercial enterprise, to the officers of justice, and to the general development of the colony, fully counterbalances, in importance, the difference shown on the debtor against the creditor side of the ledger. The importance of the telegraph has been recognised in South Australia, as elsewhere, and under the able direction of Mr. Todd it promises to become a permanent and profitable institution.

THE MECHANICAL THEORY AND APPLICATION OF THE LAWS OF MAGNETIC INDUCTION OF ELECTRICITY.*

BY J. BAYNES THOMPSON, ESQ.

IN speaking of the mechanical application of the laws of magnetic induction of Electricity, it will be necessary first to state partially, at least, the theory of that induction, and the laws included in it.

ELECTRICITY AND MAGNETISM CONSIDERED AS FORCE.

We are in the habit of speaking of Electricity and Magnetism as fluids—imponderable fluids! That is, matter without weight. As if it were possible that there could be matter either solid or fluid without weight. All matter must have gravity to whatever system it may belong; for gravity or weight means only this, that in every system of matter there is a common bond of union or centre of attraction. If electricity were a fluid it could not be induced: one fluid does not induce another. Motion may be induced in one fluid by another fluid, which is

* Read at the meeting of the British Association held at Bath, 17th September, 1864.

itself in motion, at the expense of its own motion; but this is not a question of the fluid but of the motion. Throughout all Nature there is no induction but that of motion, which is change of state or change of place. If it be internal motion, then it is change of state; if local motion, then change of place. This is self-evident almost of the force of an axiom; for matter *is*, and can only change form and position.

We have ceased to consider heat and light as matter, and it appears that all other so-called imponderables must follow these.

Heat has been considered as the internal excitation of motion in matter in general, and light as the excitation of motion in a rare medium called Æther. It is possible that this may not express the true nature of light and heat; but at least this much is settled, that light and heat are not matter, but force in act. In like manner I shall for the present call electricity and magnetism two different forms of force, for I am constrained to think of them as such.

By this means electric and magnetic induction will be reduced to a correspondence with mechanics. This is another reason why I prefer to speak of electricity and magnetism as force; for I have an impression that any scientific proposition or statement which cannot be translated into mechanical language is somehow not in accordance with facts.

The mechanical conditions of matter being the basis upon which all our knowledge is built; all our other knowledge must correspond to, and at least take the mechanical form of expression. Besides, the mechanical relations of things form the most exact part of our knowledge. In fact it is only in form and number that we have yet attained to an exact science.

ELECTRIC AND MAGNETIC CONDUCTION.

Electric conduction is considered, nay, I think, is proved beyond doubt, to be the vibration or gyration of the molecules of the conducting body, as light is of the æther, and sound of the air.

A sphere of magnetic force is the symmetrical arrangement of some medium in a vortical gyre. This is shown to us by means of iron-filings, which are arranged as meridianals; but a spiral current of electricity is necessary to produce polarity in iron, or, at least, a tangent to such a spiral, which is at right angles to such polar direction; therefore, the real magnetic sphere is in spirals, or, if complete, a vortical of spirals. This is so whether it be the sphere of an electro-magnet or a permanent magnet. This sphere can be excited in and around all substances indifferently, in air or in a vacuum—with the exception of two or three substances, which are called paramagnetics. These are magnetic conductors by pre-eminence, of which iron is the best, as silver is of electricity.

These conductors of electricity and magnetism are diametrically opposite in effect. The one needs to be insulated by a bad conductor; but the other cannot be insulated, nor does it require it, And these facts point to this conclusion: that electric action is a molecular action of particular substances, and magnetism of a general sphere or medium.

The electrical force seems to move in all directions, according to the form of the conductor; but the magnetic moves only in regular spirals. Because of this latter fact the electric conductor must be arranged in regular spirals to induce the full amount of magnetic force in iron, or to excite without iron a perfect magnetic sphere of force, and also to obtain the full amount of electric induction from such a magnetic sphere of force.

MAGNETIC EXCITATION.

If we wish to excite the magnetic force in iron, by means of electricity, we must pass a spiral current of electricity around it. Upon th[illegible] Ampere's theory of the magnet was probably based.

He, a[illegible] oned from the form of the electric current necessary to produce an electro-magnet to the molecular currents necessary to produce a permanent magnet; and these molceular currents he supposed to be electric also; but this last supposition involves the necessity of another supposition, namely, that electric currents are continually gyrating through the steel. However, as a general theory, leaving out these unproved suppositions, it appears to cover all the facts that have yet been recorded. A helix of insulated wire, enclosing an iron core, not only makes that iron a magnet when electrically excited, but is itself a magnet, and has a sphere of magnetic lines of force surrounding it, though there be no iron within.

This induced sphere of magnetic lines of force extends much beyond the exciting helix: the more intense the electric excitement, the more extended is the sphere.

ELECTRIC INDUCTION.

If another helix of insulated wire surround the exciting helix within the sphere of magnetic force, then in this outer helix there will be an electric current induced on the instant that the iron core is magnetically excited, but in the opposite direction to that from the battery which flows through the inner helix. Also when the magnetism ceases in the core there will be an electric current induced, but in the same direction as that in the inner helix. Now, why have we two electric inductions for one magnetic excitation? I think, to explain this, we must have recourse to Professor Faraday's moving wire amongst the lines of force of a permanent magnet. Here we have the lines of force and the conducting wire; but there is no electric induction without mechanical motion. Three conditions appear to be necessary: a sphere of magnetic force a conductor, and the motion of that conductor across these lines of force. But in electro-magnetic induction, the conductor is not moved across the lines of force. Neither is it in magnetic-electro induction when the permanent magnet is caused to move in front of the helices; and in both these cases the induction is double. Now, it appears, that there is only one other way in which the necessary conditions can be fulfilled, and that is, that the lines of force must move across the conductor. If this be granted, as I think it must, then the two inductions are explained. There must be one induction on the projection of the lines across the conductor, and another on their recession; and these inductions must necessarily be in opposite directions. From this there follows two consequences, that these lines of force are not in a state of fluxion except on their projection and recession; and that the electricity that excites the magnetism is in a continuous state of fluxion from the completion of its circuit to its disruption.

Not only are the molecules of iron brought into the symmetrical vortical form, but the general sphere of magnetism also, whether there be a magnetic metal present or not, and these are held in that form only whilst the electricity flows; when it ceases they revert to their neutral state. The molecules of steel, on the contrary, when once brought into that form remain in it, and sustain the external sphere of magnetic force. This magnetic force is static, no motion is apparent whilst it is maintained constant; but whilst the electric circuit is maintained constant there is in it continued action; this is proved by electrolysis. On the contrary the motion of the magnetic sphere is only on its projection and recession; that is, on its flowing into the induced vortical, and on its receding as the vortical subsides.

The projection and recession of the lines of force are the same in electro-magnetic induction and in magneto-electric induction. In the former case the core is excited by electricity, in the latter by a permanent magnet; but in all cases there must be the three conditions—a sphere of magnetic force, a conductor and motion—or there will be no induction.

CONFIRMATIONS FROM MECHANICS.

Descending now to simple mechanics for explanations and

confirmations. Taking the form of our exciting electric current (or, which is the same thing, the form of the conductor), which in mechanics corresponds to the screw or spiral incline. If two screws move, the one within the other, then the motions of the two will be in opposite directions. Now, it is not the electric current in the inner exciting spiral that induces directly the current in the outer spiral, but by an intermediate—the magnetic sphere; for it is this sphere which moves within and amongst the external spirals, there being no other nexus between the inner and outer spirals, the two being electrically insulated; but the magnetic sphere penetrates all things. Besides, if the electric induction were produced directly by the inner electric current, then, according to mechanical induction, the induced current would be continuous with the exciting current; but it is not, it oscillates with the projection and recession of the magnetic sphere.

Again, if the magnetic spiral were intact before the completion of the inner electric circuit, and not projected by it, then motion only would be induced in it, and that in a contrary direction to the exciting electric current, and it would be continuous, then the induced electric current would be in an opposite direction to that, and also continuous; for every effect must continue whilst its exciting cause continues. But these two conclusions are contrary to the fact, therefore the supposition is contrary to the fact; the magnetic sphere being projected by the inducing electric current, consequently inducing the outer electric current in an opposite direction to itself and to the inducing electric current.

In magnetising the core of an induction coil the magnetism must proceed gradually from the positive to the negative, as the exciting electric current does. It is too instantaneous for us to prove this by experiment; but we can clearly see it must be so from the nature of the case. This then will give an induction according to mechanics, in an opposite direction to the inducing current; and, of consequence, on the recession of the magnetic sphere the direction of the induction will be changed. By mechanics, then, not only the fact of induction is explained, but also the double induction, and the directions of the currents.

THEORETIC SUMMARY.

That the phenomena called electricity and magnetism are two forms of force, which may either be in conatus or in act. If in conatus, then they are in a state of tension; if in act, then in a state of fluxion. Electricity is in conatus when in the static form of excitation, or when the voltaic circuit is not completed. In act when matter highly excited is brought in contact with matter less highly excited, or when the voltaic circuit is completed.

Magnetism is in conatus when the magnetic vortical sphere is held constant by a constant electric current, or by hardened steel or magnetic iron ore, so that the earth magnetism may flow in. In act on its electric projection and recession, or when iron or some other paramagnetic is moved through this sphere.

That Electric Conduction is by certain molecular movements of particular portions of matter. Those wherein this movement is easily excited are called conductors, and those wherein it is with difficulty excited are called insulators.

That Magnetic Conduction is by the symmetrical arrangement into a vortical sphere of spirals of a general medium, which pervades all matter, and holds it in that form for the time being. That particular matter wherein the sphere is easily excited is called paramagnetic, and that wherein it is with more difficulty excited is called diamagnetic. That this sphere can be fixed by means of hardened steel or magnetic iron ore.

That the Magnetic Vortical can be excited by means of spiral currents of electricity, generally, and even by a tangent to such spiral. Also it can be induced by magnetic conduction in paramagnetics.

That the magnetic force is only in a state of fluxion on the projection and recession of this sphere.

That this sphere is projected in the direction of the exciting electric current, and recedes in the opposite direction.

That the electric force is induced on the projection of the magnetic vortical, and also on its recession. That, consequently, for one inducing current there are two induced currents; therefore it would appear, that by induction electric excitation is multiplied.

FINALLY—That these inductions and conversions of force are in strict accordance with the laws of mechanical motion.

APPLICATION OF ELECTRICITY.

When we wish to use the electric force we excite it by chemical or mechanical action, but most generally by chemical action: as for Telegraphy and Electro-Metallurgy. If for Telegraphy, then electricity of considerable *intensity* is required. To obtain this intensity a series of successive elements must be used, and these should be insulated from each other, that there may not be any useless action. Besides, to insure this, the elements must be perfectly pure also: that is, the positive element must be free from any matter that is negative to it, and the negative free from any matter that is positive to it.

All these conditions can be fulfilled. All the elements for a battery can be made pure; but they will have to be specially made so: the materials of ordinary commerce are not so. Given our materials pure and our cells perfectly insulated, still so great a number as is frequently required is not easily kept in order. Frequently as many as 500 cells are required in one battery, and in a large telegraph office five or six thousand must be kept ready for use. In such a number the waste from local action and want of insulation must be considerable, leaving out the first cost, which is not a small sum. But the great and never-ending difficulty is to keep them in working order It is the universal expression of all who have to do with batteries, that "they are a great nuisance." There are two ways of dispensing with these enormous voltaic batteries—either by using magneto-electric or electro-magnetic induction machines. The magneto is not self-acting, and this is detrimental to it. The electro-magnetic induction machine is not only much more powerful, but can be made self-acting.

THE INDUCTION MACHINE.

In the machine here exhibited this condition is fulfilled. Here are four induction coils with iron cores arranged as two electro-magnets, with their like poles facing each other, and at a small distance apart; between these a light armature vibrates, which drives a longitudinal rod, and this rod actuates the commutator, which delivers the two opposite induced currents in one; it also actuates the break-piece, which throws the battery current from one pair of coils to the other, thereby producing electric induction in the outer coils of the two pairs of spools alternately.

This induced electricity should, by theory, be equal in force at least to the indueing current; for if a certain amount of force be exerted to produce an effect, that effect is simply the embodyment of the force exerted in another form.

The only limit to the induction is the bounds of the sphere of magnetic force, or rather the useful limit will be within the point where the resistance of one layer of the conductor is equal to the force of the magnetic sphere at that point. From this it would appear that the induced electricity would come short of the inducing electricity; but there is another consideration not taken into account, namely, that there are two electric inductions for one magnetic induction. Let us see how this will affect our machine. A current of electricity is sent

through the inducing coils of one pair of spools, and produces magnetic spheres in and about the iron cores. These spheres, on their projection, produce theoretically an induced current of electricity equal in amount to that which produced them, and without any further expenditure of inducing electricity, there is another induction of equal amount on the recession of the magnetic sphere. This looks like the production of something out of nothing, which is impossible. But if looked into more closely, it will be seen that electricity does not in this case produce the magnetic force, and I suspect it never does. It simply induces a particular spiral or vortical sphere, into which the general magnetic sphere flows: this is proved to be so by the following considerations. If a piece of iron be brought into the sphere of a magnet that sphere converges and concentrates itself in it, the molecules of the iron being brought into order by the force of the magnet. Further, if a steel bar be magnetised by means of an electric current, it retains its magnetism for ever. Now, to produce a similar continued magnetism in soft iron would be at the expenditure of an infinity of electric force. Whence then comes that magnetism if not from the general Earth sphere,—certainly not from any other known force. Clearly, then, the electricity simply brought the molecules of the steel into order, and did not produce the magnetism. Similarly, then, all magnetic spheres are produced; therefore, in saying that we have two induced currents, each theoretically equal to the inducing current, we do not state an impossibility; but simply, that we can utilise by suitable mechanical contrivance a portion of that store of Earth magnetism, which to us is inexhaustible. This is the theoretic result; but, as in the theory of heat, the practical result will come short of it, but it is not liable to so many deductions. The principal deductions are these: the resistance of the conductor, and the induction which takes place in the inducing coil. Beyond these I think there is not any other. After these deductions, I am convinced, from experience, that there is a great gain on the inducing electricity expended, and in this machine there seems to me to be proof positive that it is so; for if the induced current of electricity be allowed to flow through the machine without external resistance it overpowers the battery current, reverses the magnetism in the cores, and arrests the motion of the machine, which could not be the case if the currents were simply equal; for the external helix being much further from the cores than the internal, the current in them must have a much smaller magnetical effect, and could produce no arrestation of the machine, which at present it does.

Beyond this there is this advantage, that you can take the induced electricity either in quantity or intensity simply by varying the thickness of the wire in the external coil. Hitherto induced electricity has not been used where a continuous current has been required; because till now there has been no machine suitable to reverse the alternate currents, which was also self-acting. The quantity and intensity of the current of this machine are governed by the same law as those of a battery.

It has been tested against a 60-cell Daniel's battery, the tension of which on a Peltier's electrometer was 12°, and the quantity on the galvanometer was 45°. The tension of the machine was $8\frac{1}{2}$°, and the quantity 35°. The ratio of the tensions will be as $\sqrt{12}:\sqrt{8\frac{1}{2}}$, or about 7 : 6, and the quantities as 45 : 35, or 9 : 7, so that the machine is slightly more intense for the quantity than the battery.

It has been tried on a line of telegraph between London and Dover, and it works the needle instrument very satisfactorily. To work the Morse instrument it requires a reversing key and shunt to send a slight reversal through the instrument. It will decompose nitrate of manganese through 600 miles of resistance.

For electro-deposit a large series of depositing cells is required. I have tried [illegible] 50, and at the same time a resistance of 20 miles of [illegible] wire in circuit. The resistance of these 50 cells was under a mile of such wire; therefore it would have deposited an equal quantity in each of 1,000 cells.

In five hours it deposited in each cell $3\frac{3}{4}$ grs.; for 1,000 cells this is 3,750 grs., and for one day of ten hours 7,500 grs., which is more than 1 lb. avoirdupois. The metal deposited was copper; therefore it would deposit much more silver, the equivalent of silver being 108—that of copper 31·7. The machine was driven by a 6-cell battery, each cell containing 18 square inches of zinc.

Beyond these applications, when wound with fine wire it is a much more efficient philosophical instrument than a Rhumkorf's coil, for the Rhumkorf gives only sparks; but it will give a stream of light, and in this form can be used for the electric light. I state this last from reason, and not from experiment.

The Advantages Obtained.

That this machine with a few cells can be made equal to a battery composed of any number of cells in series without the loss by leakage and local action, which is inevitable in large batteries, to say nothing of the trouble that is saved. These are great advantages, if there were no augmentation of electricity by induction. That, therefore, it is not only much more convenient, but more economical than batteries for scientific purposes and for use in the arts. Its small battery being easily kept in order and quickly put in action, and the machine itself being simple in construction is not liable to get out of order, and will not wear out for very many years.

[In the discussion which followed the reading of the foregoing paper, Mr. Fleeming Jenkin, one of the secretaries of the section, explained that magnetic machines had been constructed which, by passing magnets across the coils in the coils across the magnets, elicited streams of different degrees of intensity; but in the present machine Mr. Thompson used a battery in one part of the machine which, he said, should induce currents of varying quantity in another part, and which currents might be so combined as to be used in many experimental ways more convenient than could be obtained from the ordinary batteries. This machine, Mr. Thompson said, was thoroughly self-acting, not requiring the intervention of clockwork or any other driving force; and instead of using a battery of twenty or one hundred cells, they could by this machine obtain equal effects from five cells, and for one cell effects which in ordinary machines would require twenty cells, and by combination other effects which would require in ordinary circumstances one hundred cells.]

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

VIII.

A.D. 1832, 1833.—Dr. Schulthess, in December, 1832, delivered a lecture before the Philosophical Society of Zurich, in which he asks, "Whether such a power as that which is obtained by interrupting the electric current, and then restoring it, could not be applied in mechanical science?" and in January, 1833, he exhibited before the Mechanics' Society a machine in which this had been so far accomplished. (See *Practical Mechanic and Engineers' Magazine*, November, 1842, p. 48.)

A.D. 1833.—Mr. Saxton, in 1833, submitted his magneto-electric machine to the British Association; the coils rotate in front of the poles of a fixed magnet. (See Highton's *Electric Telegraph*, p. 17.)

A.D. 1833.—Gauss and Weber invented their electric telegraph in 1833. "One wire and one needle only were needed. The power employed was magneto-electricity." (See Highton's *Electric Telegraph*, p. 39.)

A.D. 1833.—Thomas Davenport, in 1833, suggested electro-motion. (See *Encyclopædia Britannica*, 7th edition, art. Voltaic Electricity, p. 687.)

A.D. 1833.—Sturgeon, in 1832, exhibited an electro-magnetic

engine which was capable of pumping water, sawing wood, and performing other mechanical operations. (See Dodd's *Industrial Application of Electricity*, p. 8.)

A.D. 1833.—M. Marianini, in 1833, relates a number of cases of paralysis treated by voltaic electricity. The application is by shocks, which are made to pass through the affected part, sometimes in one direction and sometimes in the opposite. In one case cited, a battery of from 58 to 75 pairs was employed. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 589, 590.)

A.D. 1834.—Dr. Faraday, in 1834, demonstrated the definite nature of electro-chemical or electrolytic decomposition, and showed that the chemical equivalents of bodies were also their electro-chemical equivalents; he also discovered that the chemical power of an electric current is in direct proportion to the quantity of electricity that circulates. (See Faraday's *Experimental Researches in Electricity*, 7th series, section 7; also *Philosophical Transactions*, 1834; also Bakewell's *Electric Science*, pp. 124-127.)

A.D. 1834.—Dr. Faraday, in 1834, established the principle that the quantity of electricity evolved from a galvanic battery depends upon the size of the plates and the intensity of the electric current upon the number of pairs. (See Faraday's *Experimental Researches*, 8th series, paragraph 991; also Dr. Golding Bird's *Natural Philosophy*, p. 227.)

A.D. 1834.—Dr. Faraday, in 1834, applied the voltameter to test the quantity of a voltaic current. (See *Philosophical Transactions*, 1834, pp. 704-741.)

A.D. 1834.—Sir William Snow Harris, between the years 1834 and 1839, applied the principle of his hydrostatic magnetometer to the electrometer. (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 85.)

A.D. 1834.—Sir William Snow Harris, in 1834, applied the common scale beam to measure electric forces. (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 86.)

A.D. 1834.—Professor Wheatstone, in 1834, found the velocity of electricity to be 200,000 miles in a second, upon the double-fluid theory of electricity, or upon the single-fluid theory 576,000 miles per second. "This fact was deduced by catching in a mirror, whilst revolving on a horizontal axis at the rate of 800 times in a second, three electrical sparks produced by the discharge of an electrical jar in an interrupted circuit, the interruptions being at each end and in the middle of the conducting wire." In this experiment the centre spark fell out of the line of the other sparks by half a degree of the circle." (See Sir W. Snow Harris' *Rudimentary Electricity*, p. 123.)

A.D. 1834.—Mr. Henry Bessemer, of Camden Town, about the year 1834, electro-deposited "copper on lead castings so as to produce antique heads in relief for mantelpiece ornaments. (See *Encyclopædia Britannica*, 8th edition, art. Electrotypie, p. 627; also *Mechanics' Magazine*, February, 1844, p. 73.)

A.D. 1834.—Professor Jacobi, in November, 1834, laid before "the Academy of Sciences of Paris a note upon a new electro-magnetic-apparatus." (See *Practical Mechanic and Engineers' Magazine*, November, 1842, p. 48.)

A.D. 1834.—Mr. E. M. Clarke, in 1834, invented a magneto-electric machine in which coils rotate at the side of the magnet. Different armatures were used for intensity and quantity currents. (See *Encyclopædia Britannica*, 7th edition, art. Voltaic Electricity, p. 693.)

A.D 1834.—Dr. Faraday, in December, 1834, experimented on the induction of a galvanic current upon itself. Professor Henry, of Princeton, United States, M. Abria, and M. Wartmann, also laboured in the same field of science. (See Faraday's *Experimental Researches in Electricity*, Vol. I., pp. 322-343; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 393-402.)

A.D. 1835.—Forbes, in 1835, employed a thermo-multiplier to measure the heat caused by the concentration of moonlight 3,000 times; the result was that no trace of heating was observed. (See *London and Edinburgh Philosophical Magazine*, Vol. VI., p. 138; also Gmelin's *Handbook of Chemistry*, Vol. I., p. 166.)

A.D. 1836.—M. Schoenbein, in 1836, made his celebrated investigations on the negative polarity induced upon iron, which renders it unattackable by acids or "passive." Dr. Faraday and M. Beetz immediately followed up these experiments, and proved that passive iron was covered with a pellicle of oxide. Mr. Andrews demonstrated the passivity of bismuth, M. Beetz that of nickel, and M. Nicklès that of cobalt. Heat, and electrolytical and chemical action under certain circumstances, are the means of rendering the above metals passive. (See Faraday's *Experimental Researches in Electricity*, Vol. II., pp. 234 and 239; and De la Rive's *Treatise on Electricity*, Vol. II., pp. 738-744.)

A.D. 1836.—Sir William Snow Harris, in 1836, published a description of "the bifilar balance electrometer," invented by himself. (See *Philosophical Transactions*, 1836; also Sir W. Snow Harris' *Rudimentary Electricity*, p. 83.)

A.D. 1836.—Chevalier Antinori, of Florence, in 1836, "by connecting a thermo-electric battery with a helix of insulated copper wire, about 500 feet in length, obtained on breaking contact, a vivid spark from the induced or secondary current produced by the passage of the primary thermo-electric current." (See Dr. Golding Bird's *Natural Philosophy*, p. 280.)

A.D. 1836.—Professor Daniell, in 1836, published an account of his "constant" galvanic battery in the "Philosophical Transactions." In this double-fluid battery the elements are, copper, acid solution of sulphate of copper, dilute sulphuric acid, and amalgamated zinc; a copper cylinder surrounds a bolt of zinc. A battery of 70 cells fused titanium and heated 16 feet 4 inches of No. 20 platinum wire. (See *Encyclopædia Britannica*, 7th edition, art. Voltaic Electricity, pp. 669-671; also Gmelin's *Handbook of Chemistry*, pp. 393 and 421; also Bakewell's *Electric Science*, pp. 43, 106, 107.)

A.D. 1836.—Mr. Mullins brought forward his "sustaining" galvanic battery in 1836. This double-fluid battery consists of copper, acid solution of sulphate of copper, solution of chloride of ammonium, and unamalgamated zinc; the zinc surrounds the copper. (See *Philosophical Magazine*, 1836, p. 283; also *Encyclopædia Britannica*, 7th edition, art. Voltaic Electricity, p. 671; also Gmelin's *Handbook of Chemistry*, Vol. I., p. 393; also *Practical Mechanic and Engineers' Magazine*, September, 1842, pp. 484, 485.)

A.D. 1836.—De la Rue published a description of his galvanic battery in 1836. This was a peculiar form of Daniell's battery in which all the cells could be filled at one time. (See *Philosophical Magazine*, 1836; also Smee's *Electro-metallurgy*, History, p. 18.)

A.D. 1836.—De la Rue, in 1836, published the following remarks in reference to the properties of his modification of Daniell's galvanic battery:—"The copper plate is also covered with a coating of metallic copper, which is continually being deposited; and so perfect is the sheet of copper thus formed, that, being stripped off, it has the counterpart of every scratch of the plate on which it is deposited." This is interesting in relation to electro-metallurgy. (See *Philosophical Magazine*, 1836; also Smee's *Electro-metallurgy*, History, p. 18.)

A.D. 1836.—Messrs. Taquin and Ettieyhausen established their electric telegraph in Vienna in 1836. The wires were partly suspended in the air and partly buried in the earth. (See Highton's *Electric Telegraph*, pp. 39 and 57.)

A.D. 1836.—Mr. Andrew Crosse, in 1836, showed his electrical arrangements to Sir Richard Phillips and other members of the British Association. These arrangements consisted of 2,500 voltaic pairs excited only by pure water, and principally employed to produce minerals artificially; also of one-third of a mile of exploring wire to collect atmospheric electricity, and suitable apparatus for its discharge and for carrying on gigantic experiments with it. Professor Sedgwick saw the atmospheric apparatus in the year 1819. Crosse also used a condenser or electrical battery, in which plates of mica separated the polar surfaces. (See Sturgeon's *Annals of Electricity*, &c., Vol. I., January, 1837, pp. 135-145; also Noad's *Manual of Electricity*, pp. 257-259.)

A.D. 1837.—Mr. Andrew Crosse, in 1837, found insects (the "electrical acarus") produced in his apparatus for electro-crystallization. (See Sturgeon's *Annals of Electricity*, &c., Vol. I., April, 1837, pp. 242-244.)

A.D. 1837.—Steinheil, in 1837, made the counting of the number of motions of the magnetic needle the basis of his telegraphic alphabet. (See Highton's *Electric Telegraph*, p. 137.)

A.D. 1837.—Steinheil, in 1837, used wires suspended in the air, and buried in the ground, for an electric telegraph. (See Highton's *Electric Telegraph*, p. 137.)

A.D. 1837.—Steinheil invented his electric telegraph in 1837. "This telegraph required only one wire and one or two magnetic needles. The power used was magneto-electricity, Steinheil had a printing telegraph as well as a means of telegraphing by sounds produced by electric apparatus striking bells." The signals of the printing or marking telegraph were made by furnishing the needles with small tubes containing ink; by the motions of the needles "dots were made on paper properly moved in front of them by wound-up mechanism; one needle making dots in one line, and the

other needle making dots in a line underneath the former." (See Highton's *Electric Telegraph*, pp. 39 and 57-60.)

A.D. 1837.—Masson, in 1837, erected a telegraph at Caen, in which magneto-electricity was made to operate upon magnetic needles. (See Highton's *Electric Telegraph*, pp. 40 and 60-62.)

A.D. 1837.—Dr. Andrews, in 1837, constructed a thermo-electric battery of platinum wires and fused salts. (See *London, Edinburgh, and Dublin Philosophical Magazine*, June, 1837, Vol. X., p. 433.)

A.D. 1837.—M. Becquerel, in 1837, invented his electro-magnetic balance. By means of this instrument the proportional intensity of galvanic currents is ascertained, weights being placed in a scale pan attached to the moveable soft iron core of the electro-magnet sufficient to restore the equilibrium. (See Sturgeon's *Annals of Electricity*, &c., Vol. I., July, 1837, pp. 398-404; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 339-341.)

A.D. 1837.—Dr. Golding Bird, in 1837, by using a constant galvanic current of low tension, decomposed fluorides of silicon, and the chlorides of potassium, sodium, and ammonium; silicon [silicium?] was thus obtained in a metallic state, and potassium, sodium, and ammonium as amalgams. (See *Philosophical Transactions*, 1837, p. 37; also Dr. Golding Bird's *Natural Philosophy*, p. 240.)

A.D. 1837.—Professor Morse says that the idea of an electric telegraph occurred to him in 1832, but he did not test his telegraph until September, 1837, and the first experiment was made October 2, 1837. In this telegraph a marking lever makes pricks on paper (a pen or pencil was at first used, the lever being actuated by an electro-magnet); one wire only is used. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 75-79; also Highton's *Electric Telegraph*, pp. 60-63.)

A.D. 1837.—Vail, in September, 1837, whilst making the Morse instrument, invented a single-wire printing electric telegraph. A type wheel is moved forward by a clockwork escapement, regulated by a pendulum, on the excitation of an electro-magnet; the paper is pressed against a type wheel, and an impression made of the letter then present. (See Highton's *Electric Telegraph*, pp. 63, 64.)

A.D. 1837.—Mr. Sturgeon, in 1837, published his investigations relating to the thickness of iron suitable for electro-magnets. Some time previous to this date he discovered "that if a bar of *soft iron* be surrounded with coils of wire, and an electric current be transmitted in the same direction through each convolution, that the soft iron bar instantly becomes a magnet, and is capable of attracting other pieces of soft iron or steel, and that it remains magnetic so long as the electric current is passing through the coils: and that as soon as the current ceases the bar instantly loses its magnetic condition, and no longer attracts pieces of adjacent iron or steel." (See Sturgeon's *Annals of Electricity*, &c., Vol. I., October, 1837, pp. 470-484; also Highton's *Electric Telegraph*, p. 27.)

A.D. 1837.—Young's single-fluid galvanic battery was invented in 1837. It consists of zinc and copper plates so arranged that a copper plate comes between two zinc plates, and a zinc plate between two copper plates; the pairs are interlaced. A mixture of dilute sulphuric and nitric acids is used to excite this battery. (See Gmelin's *Handbook of Chemistry*, Vol. I., p. 425; also *Practical Mechanic and Engineers' Magazine*, February, 1842, p. 193.)

A.D. 1838.—Mullins, in 1838, substituted sycamore porous cells (in double-fluid galvanic batteries) for animal membranes. (See Gmelin's *Handbook of Chemistry*, Vol. I., p. 422; also *Practical Mechanic and Engineers' Magazine*, September, 1842, pp. 484, 485, and November, 1842, pp. 43, 44.)

A.D. 1838.—Professor Jacobi, in 1838, "produced a vessel upon the Neva worked by electro-magnets." (See *Abridgments of the Specifications relating to Marine Propulsion*, Part. II., p. 144; also *Times* newspaper, December 26, 1857, p. 9, col. 4; also *Practical Mechanic and Engineers' Magazine*, November, 1842, p. 48.)

A.D. 1838.—M. Amyot's proposal for an electric telegraph was made to the Académie des Sciences on July 2, 1838. In this telegraph it was intended to use a single current and a single needle, "which writes of itself on the paper," the paper being moved by clockwork. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 84, 85.)

A.D. 1838.—Professor Jacobi first announced his "galvanoplastic" process in October, 1838. An allusion to it was published in this country in May, 1839; the paragraph is as follows:—"He has found a method—if we understand our informant rightly—of converting any line, however fine, engraved on copper, into a relief by galvanic process." Jacobi says that his process is applicable to copper-plate engravings, medals, stereotype plates, ornaments, and to making calico-printing blocks and patterns for paper-hangings. (See Smee's *Electro-metallurgy*, History, p. 18; also *Athenæum*, May 4, 1839; also *Mechanics' Magazine*, May 11, 1839, and February 24, 1844, p. 118; also Gmelin's *Handbook of Chemistry*, Vol. I., pp. 502-510.)

A.D. 1838.—Schweigger, in his journal, in 1838, proposes the following modification of Soemmering's electric telegraph:—The use of two galvanic batteries, one weaker than the other, so as to vary the amount of gas evolved in a given time; he proposes also to vary the period of time of the evolution of the gases. The number of wires would be then reduced to two. Printing the letters by means of lamp-black paper, &c., was also suggested. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 64, 65; also Highton's *Electric Telegraph*, pp. 48, 49.)

A.D. 1838.—Mr. J. Dancer, of Liverpool, about 1838, used porous vessels of the thinnest unglazed biscuit ware for galvanic batteries. (See Dr. Golding Bird's *Natural Philosophy*, p. 229; also *Mechanics' Magazine*, February 3, 1844, p. 76.)

A.D. 1839.—Dr. William O'Shaughnessy, at Calcutta, in 1839, made experiments on a small scale to submerge an insulated electric conductor under water; the conductor consisted of copper wire, coated with cotton thread saturated with pitch and tar. (See *Journal of the Society of Arts*, April 23, 1858, p. 351.)

A.D. 1839.—M. Vorsselman de Heer, on the 31st of January, 1839, exhibited an electro-physiological telegraph at a meeting of the Societé de Physique of Deventer. Ten wires are used, and the operator's fingers receive shocks, the signal being determined by the fingers affected; it is also proposed to use secondary currents. (See Poggendorff's *Annalen*, Vol. XLVI., p. 513; also Abbé Moigno's *Triaté de Télégraphic Electrique*, pp. 90-95; also *Journal of the Society of Arts*, April 23, 1858, p. 358.)

A.D. 1839.—Grove's galvanic battery was invented in 1839. In this double-fluid battery the elements are platinum, nitric acid, dilute sulphuric acid, and amalgamated zinc. (See Gmelin's *Handbook of Chemistry*, Vol. I., pp. 391 and 422; also Noad's *Manual of Electricity*, 3rd edition, p. 167.)

A.D. 1839.—Mr. T. Spencer, about the year 1839, in galvanic batteries, substituted a brown packing-paper porous cell for the oxgullet of Daniell's battery; also Glauber's salt or sulphate of zinc for dilute sulphuric acid. (See Gmelin's *Handbook of Chemistry*, Vol. I., p. 422; also *Instructions for the Multiplication of Works of Art in Metal by Voltaic Electricity*, by Thomas Spencer, 8vo., Glasgow, 1840, pp. 59, 60.)

The Application of Electricity to Curative Purposes.—M. Nélaton, whose reputation as a surgeon is European, has recently made a discovery, or rather applied a natural force, to the cure of one of the most painful forms of disease that afflict human nature, and he has just communicated the fact to the Academy of Sciences of Paris. The object is the destruction of tumours by means of the electric current. Polypi and other tumours formed in the natural cavities of the head and of other parts of the body are not only most painful, but their extirpation is attended with the greatest danger, especially when seated in the head. M. Nélaton has given a large amount of attention to this subject, and having arrived at the conclusion that all the means in general use were exceedingly unsatisfactory, resolved to try the effect of electricity. It has been long known that when two needles connected with the poles of a battery are placed in contact with the skin of the human body a slight destruction of the tissue occurs, but little importance was attached to the fact. M. Nélaton, however, conceived the idea of attempting to destroy tumours by inserting the needles in the parasitic mass, and placing them in communication with a powerful voltaic pile. In the first place he experimented on a dog, and he found that when two platinum points connected with a Bunsen battery of nine elements were inserted in the flesh there arose, after the current had been in action for eight or ten minutes, an induration of some extent around the positive needle and a corresponding softening of the parts round the other, with the formation of a white froth, composed of extremely minute bubbles of gas. After some other preliminary experiments, Dr. Nélaton had an opportunity of testing his new mode of operation, to which he gives the name of *electropuncture*, in the case of polypus in the human subject. A young man, a tutor, nineteen years of age, entered into the family of M. Nélaton; he was suffering from a large vascular tumour in the roof of the mouth, which caused him great pain and inconvenience. All the ordinary modes of treatment had been tried without success, when Dr. Nélaton decided on making an experiment with the electric current. Two needles were introduced into the tumour, the pain was slight, and the white frothiness soon made its appearance. The action was continued for ten minutes. The treatment was repeated at intervals of eight and ten days, and maintained, after the first occasion, for only three to five minutes; the polypus began to diminish from the first application, and the patient was cured in four months, without loss of blood, and having suffered little pain. Dr. Nélaton has achieved few more important successes.

ON BOILING WATER.

BY W. GROVE, ESQ., Q.C., F.R.S., M.R.I.

(*Concluded from page* 139.)

A similar experiment was made with melted sulphur, and sulphuretted hydrogen was given off, but not in such quantities as the phosphuretted hydrogen. I tried in vain to carry on these experiments beyond a certain point; the substance became pasty, mixed with platinum from the arc, and, from the difficulty of working with the same freedom as when they were fresh, the glass tubes were always broken after a certain time. Had I time for working on the subject now, I should use the discharge from the Ruhmkorf coil, which had not been invented at the period of these experiments. At a subsequent period, when this discharge was taken in the vacuous receiver of an air-pump from a metallic point to a metallic capsule containing phosphorus, a considerable yellow deposit lined the receiver, which, on testing, turned out to be allotropic phosphorus. No gas is, however, given off. I had an air-pump (described "Phil. Trans.," 1852, p. 101) which enabled me to detect very small quantities of gas, but I could get none. It was in making these experiments that I first detected the striæ in the electric discharge (which have since become a subject of such interesting observations), which are seen, perhaps, more beautifully in this phosphorus vapour than in any other medium, and which cease or become very feeble where the allotropic phosphorus is not produced.

I tried also phosphorus, highly heated by a burning-glass, in an atmosphere of nitrogen, but could eliminate no perceptible quantity of gas, though the phosphorus was changed into the allotropic form.

It is not difficult to understand why gas is not perceptibly eliminated in the last two experiments; the effect is, probably, similar to that described in my paper on the "Decomposition of Water by Heat," where, when the arc or electric spark is taken in aqueous vapour, a minute bubble of oxyhydrogen gas is freed and disseminated through the vapour, recombination being probably prevented by this dilution; but, however long the experiment may be continued, no increased quantity of the gas is obtained, all beyond this minute quantity being recombined. If, however, the bubble of gas be collected, by allowing the vapour to cool, and then expelled, a fresh portion is decomposed, and so on.

So with the phosphorus in the experiments in the air-pump and with the burning-glass; if any gas is liberated it is probably immediately recombined with the phosphorus; possibly a minute residuum might escape recombination, but the circumstances of the experiment did not admit of this being collected, as the gas was with the aqueous vapour.

When, on the other hand, the gas freed is immediately cut off from the source of heat, as when the spark is taken in liquids, an indefinite quantity can be obtained.

Decomposition and the elimination of gas may thus take place by the application of intense heat to a point in a liquid, or also in gas or vapours; but in the latter case it is more likely to be masked by the quantity of gas or vapour through which it is disseminated.

I believe there are very few gases in which some alteration does not take place by the application of the intense heat of the voltaic arc or electric spark. If the arc be taken between the platinum points in dry oxygen gas over mercury, the gas diminishes indefinitely, until the mercury rises, and, by reaching the point where the arc takes place, puts an end to the experiment. I have caused as much as a cubic inch of oxygen to disappear by this means. I at one time thought this was due to the oxidation of the platinum, but the high heat renders this improbable, and the deposit formed on the interior of the glass tube, in which the experiment is made, has all the properties of platinum-black. So if the spark from a Ruhmkorf coil be taken in the vapour of water for several days, a portion of gas is freed which is pure hydrogen, the oxygen freed being probably changed into ozone, and dissolved by the water in this case, while in the former it combined with the mercury.

I have alluded to the eudiometer by which I analyzed the gases obtained in these experiments. It was formed simply of a tube of glass, frequently not above 2½ millimetres in diameter, with a loop of wire hermetically sealed into one end, the other having an open bell mouth. By a platinum wire a small bubble of the gas to be examined could be got up through water or mercury into the closed end of the tube, and, by the addition of a bubble of oxygen or hydrogen gas, a very accurate analysis of very minute quantities of gas could be made. I have analysed by this means quantities no larger than a partridge-shot.

I need hardly allude to results on the compound liquids, such as oils and hydrocarbons, as the fact that permanent gas is given off in boiling such liquids would not be unexpected; but the above experiments seem to show that boiling is by no means necessarily the phenomenon that has generally been supposed, viz., a separation of cohesion in the molecules of a liquid from distension by heat. I believe, from the close investigation I made into the subject, that (except with the metals, on which there is no evidence) no one has seen the phenomenon of pure boiling without permanent gas being freed, and that what is ordinarily termed boiling arises from the extrication of a bubble of permanent gas either by chemical decomposition of the liquid, or by the separation of some gas associated in minute quantity with the liquid, and from which human means have hitherto failed to purge it; this bubble once extricated, the vapour of the liquid expands to it, or, to use the appropriate phrase of M. Donny, the liquid evaporates against the surface of the gas.

My experiments are, in a certain sense, the complement of his. He showed that the temperature of the boiling point was raised in some proportion as water was deprived of air, and that, under such circumstances, the boiling took place by *soubresauts*. I have, I trust, shown that when the vapour liberated by boiling is allowed to condense, it does not altogether collapse into a liquid, but leaves a residual bubble of permanent gas, and that at a certain point this evolution becomes uniform.

Boiling, then, is not the result of merely raising a liquid to a given temperature, it is something much more complex.

One might suppose that with a compound liquid the initial bubble by which evaporation is enabled to take place, might, if all foreign gas were or could be extracted, be formed by decomposition of the liquid; but this could not be the case with an elementary liquid; whence, the oxygen from bromine or the hydrogen from phosphorus and sulphur?

As with the nitrogen in water, it may be that a minute portion of oxygen, hydrogen, or of water, is inseparable from these substances, and that if boiled away to absolute dryness, a minute portion of gas would be left for each ebullition.

With water there seems a point at which the temperature of ebullition and the quantity of nitrogen yielded become uniform, though the latter is excessively minute.

The circumstances of the experiments with bromine, phosphorus, and sulphur, did not permit me to push the experiment so far as was done with water; but as far as it went the result was similar.

When an intense heat, such as that from the electric spark or voltaic arc is applied to permanent gas, there are, in the greater number of cases, signs either of chemical decomposition or of molecular change; thus compound gases, such as hydrocarbons, ammonia, the oxides of nitrogen, and many others are decomposed. Phosphorus in vapour is changed to allotropic phosphorus, oxygen to ozone, which, according to present experience, may be viewed as allotropic oxygen. There may be many cases where, as with aqueous vapour, a small portion only is decomposed, and this may be so masked by the volume of undecomposed gas as to escape detection. If, for instance, the vapour of water were uncondensible, the fact that a portion of it is decomposed by the electric spark or ignited platinum would not have been observed.

All these facts show that the effect of intense heat applied to liquids and gases is much less simple, and presents greater interest to the chemist, than has generally been supposed. In far the greater number of cases, possibly in all, it is not mere expansion into vapour which is produced by intense heat, but there is a chemical or molecular change. Had circumstances permitted, I should have carried these experiments further, and endeavoured to find *experimentum crucis* on the subject. There are difficulties with such substances as bromine, phosphorus, &c., arising from their action on the substances used to contain and heat them, which are not easy to vanquish, and those who may feel inclined to repeat my experiments will find these difficulties greater than they appear in narration, but I do not think they are insuperable, and hope that, in the hands of those who are fortunate enough to have time at their disposal, they may be overcome.

To completely isolate a substance from the surrounding air, and yet be able to experiment on it, is far more difficult than is generally supposed. The air-pump is but a rude mode for such experiments as are here detailed.

Caoutchoic joints are out of the question. Even platinum wires carefully sealed into glass, though, as far as I have been able to

observe, forming a joint which will not allow gas to pass, yet it is one through which liquids will effect a passage, at all events when the wires are repeatedly heated.

In some experiments with the ignited platinum wire hermetically sealed into a tube of glass, the end of the tube containing the platinum wire was placed in a larger tube of oil, to lessen the risk of cracking the glass. After some days experimenting, though the sealing remained perfect, a slight portion of carbon was found in the interior liquid. This does not affect the results of my experiments, as I repeated them with glass tubes closed at the end, and platinum wires, and also without the oil-bath, but it shows how difficult it is to exclude sources of error. When water has been deprived of air to the greatest practicable extent it becomes very avid for air. The following experiment is an instance of this:—A single pair of the gas battery, the liquid in which was cut off from the external air by a greased glass stopper, having one tube filled with water, the other with hydrogen; the platinized platinum plates in each of these tubes were connected with a galvanometer, and a deflection took place from the reaction of the hydrogen on the air dissolved from the water. After a time the deflection abated, and the needle returned to zero, all the oxygen of the air having become combined with the hydrogen. If now the stopper were taken out, a deflection of the galvanometric needle immediately took place, showing that the air rapidly enters the water as water would a sponge. Absolute chemical purity in the ingredients is a matter, for refined experiments, almost unattainable. The more delicate the test, the more some minute residual product is detected. It would seem (to put the proposition in a somewhat exaggerated form) that in Nature everything is to be found in anything if we carefully look for it.

I have indicated the above sources of error to show the close pursuit that is necessary when looking for these minute residual phenomena. Enough has, I trust, been shown in the above experiments to lead to the conclusion that hitherto simple boiling, in the sense of a liquid being expanded by heat into its vapour, without being decomposed or having permanent gas eliminated from it, is a thing unknown. Whether such boiling *can* take place, may be regarded as an open question, though I incline to think it cannot; that if water, for instance, could be absolutely deprived of nitrogen, it would not boil until some portion of it was decomposed; that the physical severance of the molecules by heat is also a chemical severance. If there be anything in this theoretic view, there is great promise of important results on elementary liquids, if the difficulties to which I have alluded can be got over.

The constant appearance of nitrogen in water, when boiled off out of contact with the air almost to the last drop, is a matter well worthy of investigation. I will not speculate on what possible chemical connexion there may be between air and water. The preponderance of these two substances on the surface of our planet, and the probability that nitrogen is not the inert diluent in respiration that is generally supposed, might give rise to not irrational conjectures on some unknown bond between air and water. But it would be rash to announce any theory on such a subject; better to test any guess one may make by experiment, than to mislead by theory without sufficient data, or to lessen the value of facts by connecting them with erroneous hypotheses.

PAPERS ON TELEGRAPHY READ AT THE MEETING OF THE BRITISH ASSOCIATION, HELD AT BATH.

ON SUBMARINE TELEGRAPHY.

On Friday, the 16th instant, Captain Selwyn read an interesting paper on the above subject, of which the following is an abstract:—The subject to which I ask your attention, is one which is full of promise, in the aid which may be given by it to the further development and more rapid increase of that social science, which is the peculiar care of this Association. I feel sure, therefore, that I shall not in vain solicit your indulgence, while I endeavour, however feebly, to aid the progress of submarine telegraphy, by pointing out possible or probable causes of the failure and loss which have hitherto been lamentably prominent features in these great enterprises for the establishment of per oceanic communication by means of electricity. It is evident that, although it may suit other powers to construct at great expense, and with many uncertainties, telegraphic wires over vast continents—wires which will no doubt some day connect the old and new worlds by principally overland system, yet that Great Britain, whose position among the nations, if not her very existence, depends on her retention of the empire of the seas, and of rapid communication with her colonies, can never be satisfied, if the nerve-like ramifications of her telegraphic system are, at any important point, entirely in the power of a foreign potentate. Therefore, the means by which electricity can be made to traverse the ocean depths, remote from chance of injury by foemen, except near the shore; where British seamen may be able to protect it, deserve even more attention in Great Britain than in any other country, and accordingly we find that a very large proportion of the submarine telegraphic cables which have hitherto been laid, or attempted, have been either planned by British energy, or strongly supported by British capital; and almost all the most important lines owe everything to these sources. There is, in short, no nation to which submarine telegraphy may not be of value, but to Great Britain it is of vital importance. Nothing has been more startling and disagreeable than the repeated failures which have, unfortunately, characterised the progress of submarine telegraphy. It seemed scarcely possible that with the names of so many engineers of acknowledged talent, with such capitalists as those who embarked in the enterprise, not only the idea, but the stern fact of repeated failures should be associated. Yet this has been the case, and I have to record a melancholy waste of capital and time, for the last ten years, in what I cannot but consider as misdirected efforts to do the right thing the wrong way. There is not the slightest reason to doubt that gutta-percha, properly laid at the bottom of the sea, in whatever depth, is a perfect and reliable insulator of electricity. A convincing proof of the durability of gutta-percha in salt water, is to be found in the fact, that many of the shallow water cables have been down for a sufficient period, ranging from eight to twelve years, to give the certainty that had there been any such disposition to decay as as was at one time feared, it would long ere this have shown itself. To what causes then are we to attribute the failures which every one laments? I answer, faulty mechanical construction of the cable and faulty mechanical arrangements for its deposition on the bed of the ocean. I tell you, engineers, that you have made a weak rope, and that you handle it wrongly on the ocean. For what reason is it a weak rope? The life of the cable, that which must not be injured in any case, is the copper wire that conveys the electricity; a stretching of this, even to the extent of one in a hundred (which, be it recollected, means, perhaps, one mile in a hundred), cannot for an instant be admitted. Yet this wire is placed in the centre of a comparatively soft and absolutely weak core, and surrounded with spirals of iron or steel by way of giving strength. The axiom of mechanics, which is here transgressed, is this—in any structure composed of spirals in combination with straight lines, any strain must first be borne by the straight lines, and elongation will take place at the limit of tensile strength. To this there is but one exception of this part of the fabric, namely, when spirals surround closely an absolutely hard straight line. The insulator which I should prefer, while admitting and fully recognising the merits of gutta-percha, is the compound of Mr. John Macintosh, of which I can confidently affirm that it will be found fully one-half cheaper than either gutta-percha or India-rubber, and nearly as much superior to either gum, whether in goodness of insulation or lowness of inductive capacity. It has too the valuable property of being absolutely indestructible either in air or earth, as well as in water. The low price of this compound is due to the fact that it is mainly composed of paraffin, forming a substance whose cheapness, insulating properties, and lowness of inductive capacity need only to be generally known to secure its adoption. No company can long afford to pay a double price for a worse material, and if, as I hope may be the case, the new Atlantic cable be laid safely next year, the demand for deep-sea cables which would be sure to follow any such success will speedily bring to the front the best and cheapest insulator. The profits of a single Atlantic cable, once laid, may be safely estimated at £600,000 per annum, even on a very low speed of transmission; and it is certain that many cables would be required to fulfil the demand for rapid and certain communication with the New World. With regard to the route which it is advisable to pursue, I am happy to say that recent discoveries of shoal water—80 furlongs, half-way, lat. 43 degs. 30 mins. N., long. 38 degs. 50 mins. W.—in the direct great circle tract between this country and the island of Bermuda make it certain that means may be found of dividing any future cable into comparatively short sections; and while I repudiate entirely the idea of anything like precipices at the bottom of the ocean, except in recently-disturbed volcanic regions, there can be no doubt that more careful consideration of the currents and winds which sweep through and over the ocean will enable us to predict (as I myself had the pleasure of doing in the case of the shoal of which I have spoken) the existence of such shoals at points. As regards the outer protection, which is in these cables, as hitherto made, a very large proportion of the whole, nothing can well be worse than the exposure of unprotected iron-wire to the certain decay from rust, which causes an item in one company's balance-sheet of £8,000 a-year for deterioration, I am of opinion that a species of vulcanized rubber coating will be found the best and cheapest protecting material. I now turn to a part of the question to which I have more especially devoted my attention during the past five or six years—the safe carrying and laying of the expensive and delicate telegraphic cable. A reel offers the most convenient and certain mode of handling a long wire or a long rope. But the enormous length which was here to be dealt with, the certainty that the weight must be enough to task the carrying of the largest known ships, led to the abandonment of the idea which did not fail, at first, to present itself—of putting the cable, when made, on a reel, which should be carried by a ship, and thence running it off into the ocean in the track of the carrying vessel. I have said little doubt, if any, existed as to the advisability of such a mode of treatment, but the carrying it into effect

seemed impossible. It was at this time that I was led to consider that, after all, a ship, in mechanics, is nothing but a floating structure designed for carrying a special cargo; and that, given any other form of cargo than that hitherto carried, another form of structure might not only be admissible, but necessary. My experience, under Sir E. Belcher, of deep-sea soundings, led to the observation that a very rapid and easy method of letting a deep-sea line run itself off is to be found by letting the reel itself afloat on the water; and many other small experiences of the behaviour of cylindrical floating bodies, either when towed or revolving, came in to assist me in arriving at the decision which I eventually adopted, which I now advocate, and for a long time past have believed to be best calculated to insure success. This consists in the employment of one or more cylindrical drums, built of sheet iron or wood, exactly as strongly put together as these materials now are in ships, with no more liability to leakage, but with the remarkable difference that here you have a ship or floating structure, which is all hermetically sealed against the influx of water from any other cause. On these drums or floating cylinders the whole cable to be laid is coiled, and owing to the great capacity or cubical contents of any cylindrical body, as much cable can be well and safely carried in this way for £5,000 as would cost, if in a ship, £30,000, or six times as much (without the safety). I might say more, for the cable which is now to be carrried by the Great Eastern could be well carried on two cylinders costing less than £8,000 each. The plan has received the approbation of many of the most scientific and distinguished members of the profession to which I have the honour to belong, and I am happy to believe that it is gaining ground with the telegraphic engineers as well. To this system it has been objected, first, that the cylinder would need to be of great size; I answer that the necessary calculations have been closely made, and that so far from this being the case, the cylinders to carry an Atlantic cable need not be longer than an ordinary canal barge, or about sixty feet, and ten feet less in diameter. That it might leak: this has been provided for by making the cylinder pump itself out, and is less likely to occur in a cylinder than any other form of naval structure. Then, that it would require extraordinary power to tow it. I have carefully experimented in this direction, and I am sure that there is no reason to fear that any speed likely to be wanted cannot be obtained. Then, landsmen have said that it would, no doubt, be economical, but how could it be managed at sea? I think it may fairly be observed that, on this head, if naval officers are satisfied, that ought to be sufficient guarantee; but I have taken some pains to disabuse those who ask these questions, not on the difficulties of their own profession, but upon those of ours. Neither my brother officers nor I would compromise our reputations by advocating a vessel that would not on the ocean do that for which we designed it; and if any of these gentlemen were told by mere seamen that they had doubts as to the arcana of engineering or electricity, I fear their patience and good nature would not prevent their indulging in a severe criticism on the presumptuous ignorance of sailors. Independently of its advantages at sea, the reel system offers so many in the preliminary treatment of a cable, and so completely protects it from the wilful or accidental damage which has sometimes been fatal, that on these grounds alone it would be worth while to build them. I am making, and shall continue to make, exertions to get one constructed; but thousands would have been saved already, if, even for a storing cable as soon as made, this plan had been put in operation. If coiling back and forth be, as almost everyone allows, the worst treatment for a conducting wire, how much might have been avoided in the present Atlantic, which is first coiled in the gutta-percha works, then in the wire covering, then into tanks on shore, then into small ships, and finally in the Great Eastern's hold, where alone iron tanks, costing as much as any cylinders could do, have to be constructed for the purpose of keeping the cable in water during the laying? Surely this is a roundabout method of doing the right thing the wrong way. Besides, after this comes the brake machinery, and cones in the coil; all to accomplish—if, indeed, it be possible—by expensive and complicated machinery, that which can be done much better by the very structure which carries the cable. This, too, in the event of a gale occurring, leaves the vessel free to separate from the cable, and watch it, or act as may be required; or if, as in the first laying of the Otranto and Avlona cable, the length should prove insufficient, the vessel may go and seek aid, or may trust to the cylinder as a buoy, relieving the cable from her own weight until assistance can arrive. I rejoice to hear that Mr. Henley has been able to pick up the end of that cable; but had he had a cylinder to lay it with, supposing that by the effects of a current he had run short of cable, he would have had nothing to do but turn round, and, towing in the opposite direction, reel up the cable, and commence *de novo*. Upwards of 10,000 miles of telegraph cables have been made and laid, and of this not one single cable, that has any title to the name of deep sea, exists which has not been repaired, while most of those which come under this denomination have ceased to exist as means of communication. The majority of cables, which are talked of and written about as successes of eminent contractors, are either massive iron, which structures it was impossible to break, or they have been broken and raised for repairs; but all are undergoing a certain, and far from slow, process of decay, which need never have been allowed had the conditions of durability been apprehended and fulfilled as they might have been. But we ought not from these facts to argue that deep-sea cables are necessary failures, or that any difficulty exists in making and laying them, which cannot be met, or will not be overcome, when public competition takes the sting from the "moral" causes of failure, which have so often been trusted at as worse than the physical difficulties. At present, as an engineering friend remarked the other day, we are in the position of the hen who sits on the newly-contrived American nest with a trap-door in the bottom. The hen turns round disposed to cluck a triumph after the manner of such birds when the operation has been performed. But lo! there is no egg there! "I thought I'd laid an egg," quoth Dame Partlett. "I thought I'd laid a cable," says the telegraphic engineer.

Mr. Fairbairn also read a paper

ON THE MECHANICAL PROPERTIES OF THE ATLANTIC CABLE.

It appeared essential to the public interest that the second attempt to submerge a telegraphic cable across the Atlantic should not be left to chance; that a close and searching investigation should be entered upon; and that nothing should be left undone that could be accomplished to ensure success. For the satisfactory attainment of this object it was considered necessary—1st. To determine, by direct experiment, the mechanical properties of cables submitted for submergence in deep water. 2nd. To ascertain the chemical properties of the insulator, and the best means to be adopted for the preservation and duration of the cable; and 3rd. To determine the electrical properties and conditions of the cable when immersed, under pressure, at great depths. These varied conditions were left to a committee, on whom devolved the consideration of every question relating to the efficiency and ultimate security of the cable. That of its mechanical properties was left in my hands, and I was requested to undertake the first division of the inquiry, and to determine by actual experiment the strengths, combinations, forms, and conditions of every cable considered of suitable strength and proportion to cross the Atlantic. To fulfil these conditions and ensure correct results a laborious series of experiments were instituted, and, in order to attain accuracy as regards the resisting powers of each cable to a tensile strain, they were broken by dead weights, suspended from a crab or crane, by which they could be raised or lowered at pleasure. The weights were laid on one hundredweight at a time, and the elongations were carefully taken and recorded in the table as each alternate fourth hundredweight was placed on the scale until it was broken. By this process we were enabled to ascertain with great exactitude the amount of elongation in seven feet six inches.

From certain considerations it was deemed advisable to select a description of cable containing this element, and all the requirements to meet the contingent forces to which it might be subjected. With these impressions on the minds of the committee, it was found desirable to select that of Messrs. Glass, Elliot, & Co., which stands highest in the order of strength. In this inquiry upwards of forty specimens of cables have been tested in their finished state, and this might have been sufficient for the committee to determine the best description of cable; it was, however, deemed advisable to investigate still further, not only the cable as a cable, but to test experimentally each separate part, in order that every security should be afforded as to the strength and quality of the material to be employed in the construction. The whole of the specimens submitted by Messrs. Glass, Elliot, & Co. were composed of the same sizes of conducting wire, insulated within alternate layers of gutta-percha and Chatterton's compound, which formed the core of each. Surrounding this core were lapped, in a spiral direction, nine, and in some cases ten wires, of ·089 to ·098 inch diameter, and each wire was covered with Manilla yarn or St. Petersburg hemp, saturated with tar and other materials. Now, as these covering wires constituted the principal strength of the cable, it was found desirable to test them separately and in combination, for the purpose of ascertaining their tenacity, ductility, elasticity, &c. The wires were of three sorts—namely, steel and iron in its homogeneous or simple state of manufacture from coke, coal, and charcoal.

From a long series of well-conducted experiments it has been found that a good quality of ductile iron improves in strength by elongation—that is, the whole of its fibres are brought into action by the elongation of those first subjected to strain, or, in other words, they yield up only part of their strength until the force reaches the other parts, so as to produce uniformity of action throughout the whole section of the wire. This is a property of good iron which requires to be extended to the manufacture of both steel and homogeneous wire, and taking the experiments as they exist in the foregoing series of results, I find that with proper care in the selection of the material in the first instance, a judicious system of manipulation in the second, and a rigid system of inspection of the manufacture, that wire of homogeneous iron ·095 inch diameter can be made of strength sufficient to sustain from 900 lbs. to 1,000 lbs., with an elongation of ·0068, or $\frac{68}{10000}$th part of an inch per unit of length. This description of iron appears to be the most suitable for the Atlantic cable, as it combines strength with ductility, and may be produced at a comparatively moderate cost. Great care is, however, required to maintain, during the whole process of manufacture, the full standard adopted at starting, both as regards the strength and ductility of the wire. It was also found desirable to test the separate strands of each cable as well as the wires themselves. For this purpose a number of strands similar to those employed in the manufacture of the different cables were produced, and the tensile breaking strain and elongations carefully observed and recorded. In order to ascertain whether the length of the lay of the hemp and Manilla round the strand was of that spiral form which produced a maximum of strength, the yarn separated from the strand was also tested, and comparing the sum of the breaking strains of the wire and yarn separately, with that of the two in combination in the strand, the object by these means was approximately obtained. Another very important question arises in the construction of this cable,

and that is, the strength of the core and its conducting wire, and how it is to be protected under a pressure of 7,000 lbs. to 8,000 lbs. per square inch when lodged at the bottom of the ocean. This appeared a question well entitled to consideration, and provided a properly-insulated wire of one or more strands can, without any exterior covering, be deposited with safety at these great depths, it is obvious that the simpler the cable the better. Assuming, therefore, that gutta-percha is the most desirable material that can be employed as an insulator, it then resolves itself into the question, what additional covering and what additional strength is necessary to enable the engineer so to pay out of a ship a length of 2,600 miles into the deepest water as to deposit it, without strain, at the bottom of the ocean? This is the question the committee had to solve, and for this very important object experiments were instituted. Regarding the circumstances bearing directly upon the ultimate strength of the cable, we have arrived at the conclusion that the cable No. 46, composed of homogeneous wire, calculated to bear not less than from 850 lbs. to 1,000 lbs. per wire, with a stretch of five-tenths of an inch in 50 inches, is the most suitable for the Atlantic cable. The following is the specification of No. 46 cable:—The conductor consists of a copper strand of seven wires (six laid round one), each wire gauging ·048 (or No. 18 of the Birmingham wire-gauge), the entire strand gauging ·144 inch (or No. 10 Birmingham gauge), and weighing 300 lbs. per nautical mile, embedded for solidity in the composition known as "Chatterton's compound." The insulator consists of gutta-percha, four layers of which are laid on alternately with four thin layers of Chatterton's compound, making a diameter of the core of ·464 inch, and a circumference of 1·392 inch. The weight of the entire insulator is 400 lbs. per nautical mile.

The External Protection.—This is in two parts. First, the core is surrounded with a padding of soft jute yarn, saturated with a preservative mixture. Next to this padding is the protective covering, which consists of ten solid wires of the gauge ·095 inch, drawn from homogeneous iron, each wire surrounded separately with five strands of Manilla yarn, saturated with a preservative compound; the whole of the ten strands thus formed of the hemp and iron being laid spirally round the padded core. The weight of this cable in air is 34 cwt. per nautical mile—the weight in water is 14 cwt. per nautical mile. The breaking strain is 7 tons 15 cwt., or equal to eleven times its weight per nautical mile in water—that is to say, if suspended perpendicularly it would bear its own weight in eleven miles depth of water. The deepest water to be encountered between Ireland and Newfoundland is about 2,400 fathoms, and one mile being equal to 1,014 fathoms; therefore, $1,014 \times 11 = 11,154 - 2,400 = 4·64$: the cable having thus a strength equal to 4·64 times its own vertical weight in the deepest water. Breaking strain, 7 tons 13 cwt. In this report we have not entered upon the process of immersion, either in tanks or the sea; we have confined our attention exclusively to the cable and the quality of the materials of which it should be composed, and the questions of coiling, shipping, submersion, &c., we have left for future inquiry.

After a few remarks from Captain Galton,

Mr. Webster said there were three points to be considered—namely, the insulation, the structure of the cable, and the mode of laying it down. With regard to the former, he thought it was a pity the covering recommended by Captain Selwyn had not been tried. It might be paid out from a hole in the bottom of the ship, and he thought the first plan, recommended by Captain Selwyn, for the construction of the cable, was a good one.

Captain Selwyn, in answer to several questions, said the cylinder he proposed was 120 feet long by 90 feet diameter, and it would carry 22,000 tons, whereas the whole weight of the present Atlantic cable was only about 6,000 tons.

A discussion ensued on the foregoing papers, in which Mr. Fairbairn, Mr. Scott Russell, and other gentlemen took part, having more immediate reference to the length of the waves of the Atlantic, and in which a general approval of Captain Selwyn's suggestions was expressed.

ANNUAL REPORT BY CHAS. TODD, Esq., SUPERINTENDENT OF TELEGRAPHS, &c., SOUTH AUSTRALIA, 1863.

(*Continued from page* 142.)

The question, however, in which the public is mainly interested, is whether persons using the telegraph should not be indemnified against loss arising from mistakes made by the operators. By clause 7 of our printed regulations, the liability of the Government is limited to £5, and that only where a message is repeated at the additional cost of 50 per cent., and the same regulation is generally adopted throughout the world; but, as I mentioned in my report for 1861, a system of insured messages has been adopted on some of the English and American lines; but on the former it is very seldom availed of by the public, and each company only holds itself responsible for delays or errors on its own lines.

The Electric and International Telegraph Company insure repeated messages (on which the 50 per cent. additional charge is paid) at the following rates:—

	£	s.	d.		£	s.	d.
For any sum up to £100	1	0	0	Above £500 to £600	6	0	0
Above £100 to £200	2	0	0	" 600 to 700	7	0	0
" 200 to 300	3	0	0	" 700 to 800	8	0	0
" 300 to 400	4	0	0	" 800 to 900	9	0	0
" 400 to 500	5	0	0	" 900 to 1,000	10	0	0

And twenty shillings for every £100, or fraction of £100, above that sum.

The company will not be responsible for any amount beyond the sum for which the message is insured and the rates paid; nor do they hold themselves liable in any case for *delays* arising from *interruptions* in the working of their telegraphs.

I think we might safely adopt a similar system on the Australian lines, although I believe it would be seldom used; but I would prefer a reduced charge—say 25 per cent. instead of 50—for repeating. Persons would then more frequently pay for having important messages repeated, and if they adopted the additional precaution of giving quotations and numbers, somewhat in the way I have suggested, I am persuaded that very few serious errors would occur.

On the Indian lines, prior to May, 1859, all private messages had to be repeated at half-price extra. Since that date it has been optional, and the repeated messages comprise about one-fifth of the whole number.

I find from a recent report of Sir W. O'S. Brooke, F.R.S., Superintendent of Telegraphs in India, that—"In an analysis of 22,657 messages transmitted at repetition price in 1858-59, it was found that 492 messages contained errors, being a proportion of one in 46 messages. The 22,657 messages contained 525,617 words, of which there were 689 erroneous, being a proportion of one error in 762 words. In 1859-60, I have ascertained that in 105,893 messages sent in Bengal, Bombay, Madras, the East Coast, Ceylon, Scinde, and the North-Western Provinces, 1,605 contained errors, being one message erroneous in every 65. The 105,893 messages contained 2,342,812 words, of which 1,982 were erroneous, being one word erroneous in 1,182."

He further adds—"The true wonder is that so few mistakes occur. The sufferer by such blunders generally appeals to the press, and cites his case as a specimen of the general working of the department. The conclusion is not just. Nothing is heard or known of the 1,182 words which have been sent correctly, while loud indignation is naturally expressed for the one error in that number."

The best operators on the Indian lines are brought from England on a three years' engagement. Before appointment each candidate is required to pass a competitive examination, and must be not less than eighteen nor more than twenty-four years of age; and must either have passed two years in the service of a telegraph company, or as an articled pupil of a telegraph engineer, or must have given special attention to chemistry and physics at some school or college recognised by the Secretary of State. The salaries commence at sums varying from £15 to £30 a month. The Morse system is generally adopted in India, but in most of the offices Sir W. O'S. Brooke has recently dispensed with the registering part of the instrument—the operators reading by sound. This he considers has enabled him to effect a large saving. Here most of our Morse operators read by sound, but I prefer retaining the register on the tape, as in case of error it enables me to ascertain whether the transmitters or receivers made it. On the whole, I believe that fewer errors occur with the Morse than with the needle system. The former is used on all our main lines; but Henley's magnetic single-needle telegraph is used for railway service and for branch offices.

I regret to find that the railway telegraph service is very inefficiently performed under the existing arrangement. Except at Adelaide and Gawler (where junior operators are employed), the instruments are worked by the railway station-masters, who each receive £30 per annum for their services as operators. This is, no doubt, an economical arrangement, but it unfortunately happens that, when most required, the telegraph is often unavailable through the absence of the officer on railway duties. And from this cause messages, both on private and railway service, are often subject to such serious detention as to render them in many cases wholly useless. The only remedy for this would be to employ junior operators at each station in addition to the station-master, who could still work the instrument in the absence of the former.

EXTENSIONS PROPOSED.

Provision has been made in New South Wales for a line from Deniliquin, viâ the Murray, to the South Australian frontier, but its erection is still in abeyance, awaiting the decision of the two Governments as to the proportions in which the receipts should be divided. Until this vexed question is settled, I fear nothing will be done towards the carrying out of a work so urgently required to perfect our system of intercolonial communication.

I am of opinion that the claim of New South Wales for two-thirds of the receipts is unreasonable, and that one-half would amply repay her for the outlay, as it would not only secure uninterrupted and more rapid communication with this colony, with which she has an increasing trade, but also satisfy the just demands of her own subjects for telegraphic communication with Wentworth. To ourselves also, as I have not failed to urge, the construction of this line is of considerable importance; it would assist our trade with the Darling, and New South Wales generally, and also afford another means of communicating with Victoria by way of Echuca, in the event of an interruption on the present intercolonial line, which more than any other is affected by atmospheric disturbances, owing to its proximity to the coast for a distance of 165 miles—between Port Elliot and Guichen Bay—where it is exposed to the full force of the gales and vapours from the Southern Ocean, which more or less affect the working of the line, even in fine weather when the wind is blowing from the sea, and frequently renders it impossible to work the two wires at the same time.

A similar difficulty was felt on the Victorian line, between Warnambool and Portland, and in erecting the second wire, provision was made for a cross line from Hexham to Hamilton, thus establishing an inland communi-

cation between Melbourne and Portland; and should it be decided not to carry out the direct Sydney line, I would recommend the construction of a line from Wellington to Border Town, to be met at the boundary by an extension from Ararat or Hamilton, and a short line from Border Town to Kincraig, which would give an independent means of communication with Mount Gambier and the other south-eastern stations. Were this done, we should very rarely have any interruption. Sydney has now a choice of three routes for communicating with Melbourne—first, viâ Albury; second, by a line branching from the first at Gundagai, viâ Wagga Wagga to Deniliquin, and joining the Victorian system at Echuca; and third, by way of Bathurst and Orange to Wagga Wagga, where it meets the second wire, thus affording ample security from all stoppages.

A line from Wellington to Border Town and Kincraig would cost about £9,000. The direct Sydney line would cost about the same, or rather more, if a separate wire were carried from Gawler Town to branch offices at Tanunda, Angaston, and Truro. It has been strongly represented to me that telegraphic facilities are much required in the districts just mentioned, where at present the agriculturists are placed at a great disadvantage as compared with those in other parts of the colony.

The following table shows the amount of business transacted last year with each of the other colonies, from which it will be seen that the business with New South Wales has increased from £2,176 0s. 9d. in 1861 to £2,833 0s. 6d. in 1863.

Table showing the Receipts on the Intercolonial Messages between South Australia and each of the other Colonies—Victoria, New South Wales, and Queensland.

Month.	Receipts on Messages between South Australia and Victoria.			Receipts on Messages between South Australia and New South Wales.			Receipts on Messages between South Australia and Queensland.

I regret that no provision has yet been made for extending our northern lines to Mount Remarkable and Port Augusta. The claims of the settlers have indeed been acknowledged, but objection being raised in Parliament to the proposal to carry out the work by means of a loan, it has remained in abevance.

(To be continued.)

CORRESPONDENCE.

THE HYDRO-ELECTRIC MACHINE.

To the Editor of the Telegraphic Journal.

Sir,—Will you, or some of your scientific readers, afford me some information as to the best form and size for a hydro-electric machine, suitable for a lecture-room. I should like the boiler and fittings, if possible, to be of such a weight that they could be moved and placed in position by two men, yet that the machine should be pretty powerful, and capable of working safely for three hours. I should also esteem full particulars respecting the best form of opening for the escape of the steam and production of the friction. Yours faithfully,

Merthyr, 15th September, 1864. W. H. Harrison.

To the Editor of the Telegraphic Journal.

Universal Private Telegraph Company, 4, Adelaide-street, West Strand, September 17th, 1864.

Sir,—In the leading article of this day's number of the *Telegraphic Journal* we find a statement that "the important position which this Company has attained is to be attributed mainly to the indefatigable exertions of the officers."

We have read this paragraph with much regret and annoyance, because we hold that inordinate encomium amounts to censure in disguise, and also because we observed with very great pleasure, at the last general meeting of shareholders, that the invaluable services of the directors were in some degree appreciated. You will oblige us by inserting this note in your next number.—We are, sir, your obedient servants,

Lewis C. Hertslet, Secretary.
Nat. J. Holmes, Engineer.

[We cannot perceive anything like an "inordinate encomium," or its equivalent, in the sentence above-quoted, which will be found to be similar to the remarks of the chairman at the last meeting of shareholders. A very nice distinction is indicated and sought to be established between the "officers" and the "directors." We hold that the directors are the *honorary*, as our correspondents are the *salaried* officers of the Universal Private Telegraph Company, and to the combined exertions of the unpaid and paid officers did we attribute the flourishing condition of the undertaking. If any other construction is placed upon our observations, it can only be by a perversion of their obvious tenour. We cannot commiserate our correspondents, as their "regret and annoyance" has been occasioned solely by their appropriation of the whole of a compliment, which was paid equally to their directors as to themselves.—Ed. *T. J.*]

AGGRAVATING FINES.

To the Editor of the Telegraphic Journal.

Sir,—As one who has experienced the annoyance of the *fining system* in telegraphy, and its utter failure to promote accuracy of transmission, permit me to suggest to the Directors, &c., the substitution in lieu thereof of a *system of rewards*, which is more in accordance with the practice followed in all other large establishments. Let those who have committed the lesser number of mistakes in the course of a year be liberally rewarded, and I venture to say that mistakes will be less frequent. Nemo.

TELEGRAPHIC NEWS.

Otrante and Avlona Cable.—This important line of telegraphic communication is now open to the public.

The Telegraph in India.—The *Times of India* announces that the telegraph line is completed between Deesa and Erinpoora, and in a forward state between Ajmere and Sojut. This portion will be completed in a few weeks.

Proposed Telegraphic Congress.—It is said that a telegraphic congress will be held in Paris on the 15th November, whereat proposals will be made for a uniform tariff, and for a reduction of charges for despatches throughout the empire.

Telegraphic Messages.—A reduction has been made in the cost of telegrams in Paris. A message can now be sent to any part of the city for fifty centimes, and the administration guarantees its delivery within half-an-hour from the time it is dispatched.

New South Wales.—The telegraph in this colony is in a declining condition. From a comparative statement of the consolidated revenue and of the special funds paid into the Treasury, at Sydney, during the quarters ending 31st March, 1863 and 1864, it appears that the receipts from the electric telegraph have decreased £1,552, or 17 per cent.

The Persian Gulf Telegraph.—It has been ascertained that the mishap to the Persian Gulf submarine cable, between Cape Monse and Gwadur, has been followed by the parting of the wire between the latter place and Mussendom. The Amberwitch, having on board a repairing staff, is on the spot, and, so soon as the weather will admit, active operations will be commenced for the restoration of this cable. It is reported that the land lines are not in a satisfactory working condition.

The New Atlantic Cable.—Active operations have been commenced during the week for the manufacture of the Atlantic telegraph cable. The construction of the core, with all the latest practicable improvements, is progressing at the works of the late Gutta-Percha Company, in the Wharf-

road, City-road, in accordance with the designs of the scientific commission. The iron wire and hempen covering, forming the exterior covering of the cable, are also in hand at the manufactory of the Telegraph Construction Company's works, under the direction of Messrs. Glass & Elliot, the contractors, at Morden Wharf, East Greenwich, a large number of artizans being employed at each of the above places for the purpose.

MISCELLANEA.

New Process of Hardening Timber.—A native of Russia has discovered a process by which timber, though newly felled, may become so hard as to resist the influences of the most trying climate for an almost indefinite period. The most curious part of the invention is that it does not involve the use of chemicals of any sort, such as steeping in creosote, &c., and that the process is applied to the tree while growing. The inventor is now making arrangements for the supply of his timber to railway contractors in England, and will not require any remuneration further than the amount which would be paid for ordinary timber, until the period shall have elapsed beyond which the ordinary railway sleepers and telegraph poles, &c., require to be replaced. The best railway sleepers require renewal at intervals of from four to six years, but the inventor of the new process asserts that he will supply an article which need not be disturbed for fifty years.

The Magnet.—A correspondent in *Notes and Queries* forwards the following interesting extract from "Pseudodoxia Epidemica, or Inquiries into Vulgar and Common Errors," concerning the magnet:—"But certainly false it is what is commonly affirmed and believed, that garlick doth hinder the attraction of the loadstone; which is, notwithstanding, delivered by grave and worthy writers, by Pliny, Solinus, Ptolemy, Plutarch, Albertus Mathiolus, Rueus, Langius, and many more. An effect as strange as that of Homer's moly, and the garlick the gods bestowed upon Ulysses. But that it is evidently false many experiments declare; for an iron wire, heated red hot, and quenched in the juice of garlick, doth, notwithstanding, contract a verticity from the earth and attracteth the southerne point of the needle. If also the tooth of a loadstone be covered, or stuck in garlick, it will, notwithstanding, attract and animate any needles excited and fixed in garlick, until they begin to rust, doe yet retaine their attractive and polary respects."

Curious Facts about Water.—The extent to which water mingles with bodies apparently the most solid is very wonderful. The glittering opal, which beauty wears as an ornament, is only flint and water. Of every 1,200 tons of earth which a landholder has in his estate, 400 are water. The snow capped summits of Snowdon and Ben Nevis have many million tons of water in a solidified form. In every plaster-of-Paris statue which an Italian carries through our streets for sale, there is one pound of water to every four pounds of chalk. The air we breathe contains five grains of water to each cubic foot of its bulk. The potatoes and the turnips which are boiled for our dinner have in their raw state, the one 75 per cent., the other 90 per cent. of water. If a man weighing 10 stone was squeezed flat in a hydraulic press, 7½ stone of water would run out, and only 2½ of dry residue remain. A man is, chemically speaking, forty-five pounds of carbon and nitrogen diffused through five and a half pailfuls of water. In plants we find water thus mingling no less wonderfully. A sunflower evaporates one and a quarter pints of water a-day, and a cabbage about the same quantity. A wheat plant exhales in 172 days about 100,000 grains of water. An acre of growing wheat, on this calculation, draws and passes out about ten tons of water per day. The sap of plants is the medium through which that mass of fluid is conveyed. It forms a delicate pump, up which the watery particles run with the rapidity of a swift stream. By the action of the sap, various properties may be communicated to the growing plant. Timber in France is, for instance, dyed by various colours being mixed with water and poured over by the roots of the tree. Dahlias are also coloured by a similar process.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2250. W. Chubb and S. Fry, improvements in the means or method of effecting communication between passengers, guards, and engine-drivers of railway trains.

2254. A. Bertsch, improvements in lightning-conductors, for preventing atmospheric electricity damaging electric telegraph instruments.

2255. R. T. Hall, improvements in the means of communicating between passengers and guards in railway trains.

2256. M. L. J. Lavater, improvements in the manufacture of driving straps or belting and of tubes of vulcanized india-rubber, and also in the manufacture of the helical coils of wire commonly inserted in vulcanized india-rubber tubes, also in desulphurizing articles of vulcanized india-rubber.

2260. J. H. Simpson, improvements in printing by electricity for telegraphic and other purposes.

2280. J. Adams, improvements in the means of communicating or signalling between the different parts of railway trains.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2075. T. Wray and R. Robinson, improvements in apparatus to facilitate communication between passengers, guards, and engine-drivers, travelling by railway trains.

2147. J. H. Johnson, improvements in apparatus for sounding alarm or signal bells.—A communication.

2151. J. S. Guy, improvements in apparatus for enabling passengers travelling by railway trains to communicate with the guard and driver.

PATENT SEALED.

680. W. A. von Kanig, improvements in railway telegraphs and signals, and also in the permanent way and carriages for preventing railway accidents.

PATENTS WHICH HAVE BECOME VOID.

2234. M. Henry, improvements in apparatus for signalling on railways by means of electricity.

2341. B. Sharpe, improvements in electric telegraph cables, and in the apparatus used for paying out such cables.

NOTICE TO PROCEED.

1336. W. Clark, improvements in electro-magnetic and magneto-electric apparatus, and their application as a stationary or locomotive driving power.—A communication.

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

1386. A. V. Newton, improvements in the construction of and mode of working telegraphic apparatus.—A communication to him from abroad by Giovanni Caselli, of Florence, in the kingdom of Italy.—25th September, 1861.

TO CORRESPONDENTS.

L. N.—As our correspondent has written in his own name, it is but fair that he should be in possession of yours, as the subject is one which interests him personally.

A Reader.—We have not yet been able to ascertain the cause of interruption to the working of the Persian Gulf telegraphic cable. It is believed that as soon as moderately fine weather sets in communication will be restored, as the steamer Amberwitch, with a competent staff and all the necessary implements on board, is at Kurrachee, according to the reports received by the last mail.

D. Parry.—We do not recommend the so-called *cheap electric bells* for domestic purposes, as they are liable to be continually out of order; besides, they are generally constructed by persons ignorant of electrical action.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—
Quarterly, 4s. 4d. | Half-yearly, 8s. 8d. | Yearly, 17s. 4d.

RAILWAY ACCIDENTS.

There is many a useful lesson to be learned from a careful consideration of the causes which have led to a railway accident. The public mind is usually so inflamed with the garbled and inflated accounts of the calamity in the public papers, that calm investigation at the period of the accident is impossible. The accounts we peruse in the metropolitan press are usually elongated reports from anxious penny-a-liners, whose chief object is to lengthen the report to its extreme limit. They are penned by those totally ignorant of railway management and railway details. The evidence of excited eye-witnesses is implicitly believed and carefully noted. Every railway official is condemned and the public mind prejudiced. This even extends to our courts of justice. The *ex parte* statements of flowery counsel, and the questionable taste of an usually impartial tribunal, rendered the trial of the driver of the train that produced the mischief at Egham a perfect farce. There was neither reason nor justice in the remarks that were made on that occasion, and the exoneration of the driver from responsibility has effected more serious danger to railway travelling than the efforts of a whole lifetime can repay. Judges and counsel may be very good lawyers, but they are no railway workers, and the one is just as much a profession as the other—*ne ultra suter crepidam.*

When, however, the details of an accident are forgotten, and when an unprejudiced account is given of the causes that produced, and the effects that resulted from, an accident, then we can arrive at an impartial view of the case. Every accident that occurs upon any railway in the United Kingdom is immediately reported to the Board of Trade. The Committee of the Privy Council of Trade at once instruct one of their inspectors—usually officers of the Royal Engineers, and men of great experience—to inquire into the details of the case. A very careful investigation is made on the spot into every particular, and an elaborate report presented to the Board, giving a true statement of the causes that led to the accident, of the effects it produced, and making suggestions to remedy the repetition of similar disasters. These reports are periodically printed, and presented to both Houses of Parliament, and can be purchased for a very small figure at the Parliamentary Paper-office. They are well worth reading. They contain, not only an accurate account of every railway accident, but they form an excellent commentary upon railway management. They keep railway managers *en courant* of new ideas and approved inventions; and though it may be impossible and impolitic to carry out all the suggestions emanating from these gentlemen, still much benefit must accrue from a careful consideration of their ideas. We have the reports for the year 1863 before us, and many a useful lesson will their perusal convey. We will open the report, and take the first case that presents itself.

An accident took place on the 11th of July, 1863, upon the Lancashire and Yorkshire Railway, near Sowerby-bridge Station. Two passenger trains came into violent collision, and fourteen persons were more or less seriously injured. Colonel Yolland was sent down to inquire into the matter, and we reprint the greater portion of his report:—

Immediately adjacent to Sowerby-bridge Station, and west of it, there is a tunnel of about three-quarters of a mile in length, and the station is protected in that direction by a distant signal worked through this tunnel, and as an additional security a signalman's hut is placed a short distance further west, with a semaphore signal close to it, and the signalman works another signal 1,190 yards distant from the hut towards Luddenden-foot Station. The signalman in this hut regulates his semaphore and distant signals by the indications of the distant signal which is worked from the Sowerby-bridge Station. The distant signal worked from the hut can be seen from Luddenden-foot Station, which is nearly one mile and three-quarters west of Sowerby-bridge Station, or about 850 yards before the signal is reached; and the semaphore signal at the hut can be seen by the driver of a train as he passes the distant signal, but it is not continuously seen owing to buildings and the nature of the ground, and a curve and cutting on the line; it is also seen at a distance of 600 yards, but is again lost sight of in the cutting. The line falls towards Sowerby-bridge Station on an easy gradient of 1 in 377.

It appears that on the afternoon of the 11th instant the 2 p.m. Manchester train, consisting of engine and tender and sixteen vehicles, including two break-vans, on passing Luddenden-foot Station found the distant signal worked from the hut on at danger, and the driver says that he shut off his steam, and whistled for the breaks, *but did not stop at the distant signal, which he should have done according to the regulations,* but slackened speed and stopped at the signalman's box at 3.34 p.m. Shortly afterwards an East Lancashire train, which left Accrington at 2.40 p.m., followed the Manchester train, passed the Luddenden-foot Station, where the all-right signal was exhibited, and found the distant signal worked from the hut on at danger against it. This train consisted of engine and tender and three carriages, two of them fitted with Newell's continuous breaks, and worked by one guard. The driver of this train admits that *this distant signal was on against him,* and says that it always is on against this particular train when the Manchester train is in front, and that he ran cautiously down until he got under the bridge, where he could see the rear of the Manchester train, and then he whistled for the breaks, and did all he could to stop, by causing the fireman to put on his break, but did not succeed in doing so before he had run into the Manchester train, at a speed which he estimates at four or five miles an hour, but which another witness thought was fourteen or fifteen.

He says he thinks he was running about thirty miles an hour as he passed Luddenden-foot Station. The signalman at Luddenden-foot Station stated that there was an interval of six minutes between the passage of the two trains at that place, and an entry to that effect is found in the train-book; *but it is admitted that the entry was not made until half-past four o'clock,* when *the collision was known to have taken place,* and it is certain that the times entered could not be absolutely correct, although they might show the interval of time between the two trains. Other witnesses state that the Manchester train had not stopped more than one or two minutes before the East Lancashire train arrived and ran into it. The two trains are timed to arrive at Sowerby-bridge Station at an interval of five minutes apart.

The book of rules of the Lancashire and Yorkshire Railway Company direct that the danger signal at a station is to be exhibited for five minutes after the passage of a train, and then the caution signal is to be exhibited for another five minutes; and drivers are directed to *stop* at an auxiliary or distant signal, and then to draw cautiously inside it. But it appears that at Luddenden-foot Station the first rule is not obeyed, as the station-master, in answer to a complaint made by the guard of this same train that he had been detained at this station, wrote an explanation to the superintendent of the district that the East Lancashire train had been detained because the Manchester train had only been gone a minute and a half; but that in future he would not detain the train, but tell the signalman to give a caution signal, and trust to his being stopped by the signalman at the hut. It does not appear that this letter was ever answered, and the signalman did not give any caution signal to the East Lancashire train, but exhibited an all-right signal.

The signals at the hut, and the distant signal worked from it, were put up for the better protection of Sowerby-bridge Station last March, and the driver of the East Lancashire train stated that he obeyed the rule, which directed the driver to stop at the distant signal, for about a week after it was put up; but when he found that the semaphore signal and the distant signal always worked together—which they were intended to do—he ceased to do so; *and the signalman at the hut allowed that he never knew a driver obey that order.*

The rules and regulations of the company are drawn up in order to secure the safety of the public travelling on railways, and to protect the railway company from the serious cost of collisions and accidents; but it is perfectly hopeless to expect that these objects can be secured if the discipline on the line is not maintained and the regulations upheld.

If there are a sufficient number of efficient inspectors employed on the line

these infractions of the rules cannot happen without their shutting their eyes and omitting to report them; but the fact is, that infringements of the regulations are considered of no importance, unless an accident occurs.

The collision was produced by wilful disobedience of the regulations of the company by the engine-driver of the East Lancashire train, and the only surprising circumstance is, not that a collision has occurred, but that with such a lax mode of working more frequent collisions do not occur.—I have, &c.,

W. Yolland,
Col. Royal Engineers.

The Secretary, Board of Trade, Whitehall.

The italics in the above extract are our own. It will be seen, in the first place, what an utter disregard of regulations and instructions was exhibited by the driver. The distant signal was on against him, and yet he drove past it. This is a sample of that recklessness and habitual carelessness which is the true cause of half of our railway accidents; and this is the class of men from whose shoulders the wise tribunal at Guildford would shift the responsibility of urging trains and carrying lives. This happy driver naïvely stated that he obeyed the rule for about a week, and then invariably neglected it. Yet is the executive not wholly blameless for allowing such laxity to exist in the carrying out of their rules, and Colonel Yolland's strictures will be fully endorsed by every thinking man.

Another lesson to be learned from this accident is the utter worthlessness of record-books, unless strictly maintained and periodically examined. It is extremely rare to find any reliable statement made of correct entries being found in these books during times of accident, and it is far more frequent to find them falsified. Indeed, it is questionable whether record-books are of any service, for they always offer a ready means for careless men to screen their neglect, and carry on their duties in a slovenly manner. The Government inspectors, however, invariably urge their employment, and few railway companies carry on their service without their aid.

The futility of working heavy traffic on the "time" system is equally evident; and we need not repeat our arguments upon this point, having so recently discussed the relative superiority of the "time" and "space" systems.

We would, in conclusion, point out the evident danger that arises from a multiplicity of signals. We have here three signals used to effect what could easily be done by one. The object was to extend the Sowerby-bridge distant signal to Luddenden-foot Station for the better protection of the line between the two stations and Sowerby-bridge itself. For this purpose three signals, habitually worked in unison, were employed. The drivers, finding that they were always alike, followed only one, and that, of course, the furthest and most dangerous. An electric signal, such as Preece's semaphore, placed at Luddenden-foot Station, and worked from Sowerby-bridge, would dispense with the use of the hut, the man, the semaphore, and the distant signal near that station. Considerable expense would be avoided, and improved efficiency result. Railway managers, rather than use electricity—which they will not comprehend—go on depending upon line signals and fallible human agency until their over-caution produces actual mischief. In the multiplicity of signals there is danger.

RESISTANCE OF VOLTAIC BATTERIES.

By Cherokee.

It is wonderful what extraordinary things one finds in print, even in scientific books, or, rather, pseudo-scientific books—things put down in such a grave and serious manner, that there is no doubt the person performing the trick thinks that he has done something, and his brethren-in-seeming take it for granted, and go on repeating it without exactly knowing why. There is an extraordinary book made by a Dr. Noad out of a collection of eleemosynary electric scraps. These he serves up in a thin sauce of his own as an omnium pudding. I certainly do admire his alms-basket for its collection of scraps; but the cooking and the sauce are to the last degree bad. So much for Dr. Noad's book and its inconsequential conclusions. I read it as a duty because it was presented to me; but what I mention it for is his explanation of the laws of the electro-motive force and resistance of batteries. First he quotes "Ohm's Law," which is, of course, a plum in his pudding; then he tacks on to it a general law drawn from it by Professor Wheatstone—such a general law!

The electro-motive force of a battery of n cells is represented by this formula—

$$f = \frac{n\,E}{\frac{n\,R\,D}{S}}$$

Where E is the specific electro-motive force of the elements used, R the specific resistance of fluids, D the distance of the plates or thickness of the fluids, and S their sectional area, f is the electro-motive force of the battery. He says this formula leads to the following general law (Wheatstone, *Phil. Trans.*, 1843):—

"1°. The electro-motive force of a voltaic circuit varies with the number of the elements, and the nature of the metals and liquids, which constitute each element, but is in no degree dependent on the dimensions of any of their parts.

"2°. The resistance of each element is directly proportional to the distance of the plates from each other in the liquid, and is also inversely proportional to the surface of the plates in contact with the liquids."

After making this quotation the Doctor leaves it without making any comment—as much as to say, "There, if you don't see the thing clearly now, there is no help for you!" My dear Doctor, we do see it clearly—quite through it, and also see that there is nothing in it. A general law you call that, do you, drawn from the above equation? yet the first part does not agree with the equation, and the second part is merely putting the fraction $\frac{R\,D}{S}$ into words, and that rather clumsily; but as a rule for guidance in any such matters it is a delusion. In 1° it is said that the electro-motive force has nothing to do with the size of the elements. I know that this is the gospel according to those who know a thing or two; but it is not according to this formula at any rate—

$$f = \frac{n\,E}{\frac{n\,R\,D}{S}};$$

for when S varies, I fancy f will vary also. If S be doubled then $\frac{n\,R\,D}{S}$ will be half what it was; consequently, f will be double what it was. This is according to the formula from which this so-called law is said to be drawn, but clearly is not. I fancy he had a confused something in his mind about quantity and intensity, and battery resistance and size of element, which could not easily be disentangled; and so to save trouble tacked it on to "Ohm's Law."

I have also seen it stated—and I think in this book, too—that a battery will do the most work when the external resistance is equal to the battery resistance. Now really I am sorry for it, but I must question that also. No doubt it may be true where the arrangement is adjusted to that end; but certainly it is not generally so, for by increasing R or D you diminish f; but f is the direct power to do work which is here diminished, and at the same time the work to be done increased.

Our Doctor seems to have been dreaming about something of this kind, from what he has put down on the page preceding the one from which I have just quoted. He says:—"By increasing the number of elements of a voltaic series we increase the tension, urging the electricity forward; but then at the same time we increase the amount of resistance offered by the liquid portion of the circuit; so that, provided in both cases the circuit be completed by a perfect conductor, as a stout copper wire, *we obtain precisely the same results in both cases*,

*the electro-motive forces and the resistances being increased by an equal amount,** for

$$\frac{E}{R} = \frac{nE}{nR}."$$

It is true that $\frac{E}{R} = \frac{nE}{nR}$; but surely he does not believe that the electro-motive force of one cell is equal to that of n cells; certainly it is possible to make it so, but it is not a general law. If it were so, then it would be absurd to use more than one cell in any battery.

But here is the Doctor's reason for using more than one cell in a battery:—"But it is very different when the circuit is closed by an *imperfect* conductor, for a resistance which might weaken to a considerable extent $\frac{E}{R}$ might not sensibly diminish $\frac{nE}{nR}$; and in accordance with this, we find that when resistances have to be overcome it is necessary to increase the number of elements in proportion to those resistances."

He says it is very different when the circuit is closed by an imperfect conductor. Now, I should like to know what makes it very different, or at all different. Is not the same resistance supposed to be opposed to both $\frac{E}{R}$ and $\frac{nE}{nR}$, whether the conductor be good or bad. The Doctor says it may diminish $\frac{E}{R}$, but it may not sensibly affect $\frac{nE}{nR}$; but he does not say how this difference is to be brought about. Let us see: let m be the resistance opposed to each, and the Doctor says the result will be $\frac{E}{R} - m < \frac{nE}{nR} - m$, but $\frac{E}{R} = \frac{nE}{nR}$ and $m = m$, and if equals be taken from equals, the remainders will be equal. But perhaps the Doctor had no little boy fresh from his Euclid to tell him that, so he gravely tells that, in accordance with this, a number of cells is used when we want to overcome resistance.

Did ever mortal man flounder about like that out of one absurdity into another? It would have been far better if the Doctor had stuck to his blue pill and black draught, than attempt to teach us the laws of electricity, which he does not appear to know much about himself. Certainly there is some truth mixed up with all this, as there is usually with that which is false and absurd. Ohm's law is certainly true; but it does not fit into the Doctor's explanations. Somehow, it will not mean what the Doctor wishes to make it. I suspect he was entirely bothered with his terms—positive fluid, negative fluid, tension, electro-motive force, intensity, quantity, cathode, anode, anion, catheon, composition of the two electricities, &c., enough to muddle anybody, and the Doctor deals in all these largely and a long list more. Why, it is an enormous labour in itself simply to repeat all these "tall" words.

In looking over different books on electricity to find a formula by which to calculate the internal resistance of a battery, I came upon these quotations, but did not find the formula either there or elsewhere in such nice form as our layers-down-of-the-law are used to put things; so I will just put down the following for discussion, by the extra learned. I do not propose to consider the resistance of the cell wherein the electricity is generated; but the resistance it experiences in a series, or battery, after it is generated; for it is clear that electricity must first be generated before it can experience resistance. It is not so much that we want to know the internal resistance of a cell, as what the effect will be of adding cell to cell in a series; therefore on this view of the matter there will be in a series of n cells a resistance of $n - 1$ cell to each cell in the series.

Let one cell give $a°$, and n cells $b°$, and let the resistance of one cell to the current be $x°$,

$$\text{Then } na - \frac{n}{2}(n-1)x = b$$

$$na - \frac{n^2 - n}{2}x = b$$

$$\frac{n^2 - n}{2}x = na - b$$

* Our italics.

$$\text{And } x = \frac{na - b}{\frac{n^2 - n}{2}} = 2\frac{(na - b)}{n^2 - n}$$

$$\text{Therefore the resistance of } n - 1 \text{ cell} = \frac{2(na - b)}{n^2 - n}n - 1 = \frac{2(na - b)}{n}$$

$$= 2a - \frac{2b}{n}$$

Now, taking this resistance from $n\,a$, we have

$$na - 2a + \frac{2b}{n} = b$$

$$(n-2)a = \frac{(n-2)b}{n}$$

$$na = b$$

So that $$-2a + \frac{2b}{n} = 0$$

That is to say, the resistance equals nothing—beats the Doctor that! Will some of your readers, "*who know about these things*," tell me where the error is?

COMMUNICATION BETWEEN GUARDS AND DRIVERS.

Nearly ten years ago there was the same sensation upon this subject as there has been during the last few months, owing to the lamentable accident at Egham. The result may also be said to be the same. Railway managers are not convinced that communication between passengers and guards is necessary. Indeed, our rolling stock is so constructed that such communication would be highly dangerous to the guards. To render such a communication practical, we must alter the whole of our rolling stock, and station-platforms. And who is the man who would recommend such an expensive undertaking for the sake of avoiding the minute number of accidents that have arisen from the absence of such a thing?

As one of the most practical schemes that were then suggested and tried, we commend the following to our readers, many of whom will recognise its author. It was found impracticable from the fact, that while the engine drivers' whistle was distinct and clear in the guards' van, the guards' whistle was comparatively inaudible on the engine, owing to the loud clamour of the train destroying the sound. It must be recollected also, that while the guard runs into the sound the driver runs out of it.

There are many simple and effective schemes in existence to effect this object, mechanical and physical. The difficulty does not lie in effecting the communication, but in convincing railway officials of its utility. Let them once say that such a plan is wanted, and give the guard access to the train, we could acquaint them with dozens of practical and economical schemes for the purpose; indeed, the patent list is inundated with them. We leave Mr. Brittan's plan to the judgment of our readers:—

"At a time when the public mind is so occupied as it is at present, on the subject of the importance of establishing a communication between the guard of a railway train and the driver of the engine, with your permission I will offer a few remarks on the subject, and then describe, as far as I am able, something which, I think, would obviate the difficulty.

"Without professing to understand one tenth part of the schemes ingenuously recommended for the above purpose, I know of none which does not involve the necessity of extra attention, to a greater or less extent; and while the plan I will lay before you is not free from the same objection, yet I think, upon examination, it will be found to approach nearer to a self-acting and efficient arrangement than anything I have hitherto seen or heard of.

"From my observations of the manner in which railway business is transacted, the small amount of time to spare at almost every station, and the liability of railway officials, in common with other people, to forgetfulness of even important duties, I feel satisfied that one of the most essential elements in the contrivance must be such a simplicity as to render it almost

unimportant whether the subject is thought of by the officials or not.

"I am satisfied that all arrangements of an electrical character are also liable to objections, on account of the liability to derangement, and the generally delicate character of the apparatus used, and to the difficulty, when changes take place among the carriages, of ensuring, on the re-union of the carriages, a perfect circuit.

"What I would propose for the purpose is this, as follows:—To the axle of the guards' brake let there be fixed a strong pinion, which will, of course, revolve as the train moves on; near this pinion will be a strong wheel, capable of being brought into gear by the guard instantaneously. On the axis to which this wheel is fixed is a crank, which works an air-pump, which air-pump fills a wind-chest, which wind-chest has a valve capable of being acted upon by a spring, or weight, so as to act as a safety-valve. By this means, I see no reason why an amount of power, equal to the task of blowing a whistle, or whistles, may not be obtained, capable of being heard by the engine-driver of the longest trains, and under the most unfavourable circumstances.

"Having once established the foregoing principle, the arrangement of codes, &c., would be very easy. The following has struck me as very safe and simple:—Let there be two whistles, of an octave difference in their tones, and then take the code as now used in our printing telegraph; let the upper notes represent our dot, and the lower notes our dashes. By the engine-driver listening and counting the number of each note, he will be able to be spoken with upon any subject, he giving "understand" or "repeat" by the whistles he has now in use on the engine. I am so satisfied of the practicability of such a plan, that I have no doubt that two telegraph clerks would be able to hold a conversation any distance, after having had half-an-hour's practice."

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

IX.

A.D. 1839.—Mr. T. Spencer, on May 8, 1839, gave notice to read a paper on the "Electrotype process" to the Liverpool Polytechnic Society: this paper was read September 12, 1839. The experiments resulting in this discovery were begun in September, 1837. The invention comprises the following points:—1st. "To engrave in relief on a plate of copper." The plate was etched by the ordinary etching process, and copper electro-deposited in the sunken lines, so as to stand out in relief. 2nd. "To deposit a solid voltaic plate, having the lines in relief." An electrotype cast is taken of an engraved plate; as the lines are sunken in the plate, they are in relief in the electro-cast. 3rd. "To procure fac-similes of medals, &c." According to one method, an electro-mould and electro-cast from that mould was taken; and according to another method, a leaden mould was taken by pressure, and an electro-cast from that mould. 4th. "To obtain a voltaic impression from a plaster or clay model." The object was rendered conducting by means of "bronze powder," or gold leaf, and an electro-cast taken. 5th. "To obtain any number of copies from an already-engraved copper plate." A copper-plate is engraved in the usual way, an impression of it is obtained in sheet lead by pressure, and an electro-cast taken from the lead. It is besides stated that iron castings may be preserved from the weather by an electro-coat of copper. The single-cell process is used. The subject was afterwards brought before the meeting of the British Association at Birmingham in 1839, and numerous specimens were exhibited, thus attracting the attention of the public to this application of electric force. (See *An Account of some Experiments made for the Purpose of ascertaining how far Voltaic Electricity may be usefully applied to the purpose of Working in Metal*, by Thomas Spencer, Liverpool, 1839; also *Mechanics' Magazine*, November 23, 1844, p. 367; also Bakewell's *Electric Science*, p. 176.)

A.D. 1839.—Mr. C. J. Jordan, on May 22, 1839, communicated the results of his electro-metallurgical experiments to the editor of the *Mechanics' Magazine*, and the letter appeared in that periodical on June 8, 1839. These experiments were begun in the commencement of the summer of 1838, and they were made "with a view of obtaining impressions from "engraved copper plates by the aid of galvanism." A single-cell arrangement was employed to obtain an electro-cast from an engraved copper plate. The application of electro-metallurgical processes to various useful purposes was also suggested. (See *Mechanics' Magazine*, June 8, 1839; also *Jordantype, otherwise called "Electrotype,"* by Henry Dircks, London, 1842; also *Contributions towards a History of Electro-metallurgy*, deposited in the Patent Office Library, January, 1859, by Henry Dircks.)

A.D. 1839.—Colonel Pasley, in 1839, proposed to the Admiralty to blow up the wreck of the Royal George, which had been submerged for sixty years at Spithead, by electro-blasting. Brass guns of sufficient value to pay for all Colonel Pasley's operations were recovered. (See Dodd's *Industrial Applications of Electricity*, pp. 14, 15.)

A.D. 1839.—Dr. Golding Bird, in 1839, noticed that the platinum plates of a voltameter, already polarized by connection with a galvanic battery, when connected with an amalgamated zinc plate immersed in the acidulated water, would evolve hydrogen in unequal volumes, one nearly twice as much as the other. (See *Philosophical Magazine*, 1839; also Dr. Golding Bird's *Natural Philosophy*, pp. 238, 239.)

A.D. 1840.—Professor Wheatstone, at the commencement of the year 1840, invented his "chronoscope," or instrument for measuring the duration of small intervals of time; this instrument has been applied to measure the velocity of projectiles. It is composed of a clock movement, set free at the moment of the ball's exit from the gun, and stopped when the ball reaches the target. For this purpose a wire in the galvanic circuit, at the gun's mouth, is broken at the instant the ball passes out of the gun; the circuit is completed when the ball reaches the target. The galvanic current acts on the clock movement by means of an electro-magnet. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 142-150; also De la Rive's *Treatise on Electricity*, Vol. III., p. 484.)

A.D. 1840.—Mr. Murray, in January, 1840, used plumbago to make non-conducting surfaces conducting, so as to enable metallic copper to be electro-deposited upon them. (See Smee's *Electro-metallurgy*, History, pp. 21, 22.)

A.D. 1840.—De la Rive, in 1840, made known the process of electro-gilding employed by him in 1828. Platinum and silver wires were electro-gilt "by employing them as negative electrodes in a solution of chloride of gold." (See De la Rive's *Treatise on Electricity*, Vol. III., p. 546.)

A.D. 1840.—Professor Jacobi, in 1840, used a modification of Daniell's constant galvanic battery, consisting of a lead or copper cylinder, with thin earthenware to separate the fluid elements; the zinc is in the centre. (See Gmelin's *Handbook of Chemistry*, Vol. I., p. 422.)

A.D. 1840.—Mr. William Armstrong, of Newcastle, in 1840, successfully experimented upon the electricity of effluent high-pressure steam; the result was the hydro-electric machine. Faraday proved that the electrical excitement is due to the friction of the particles of water against the sides of the jet whence the steam issues. (See Bakewell's *Electric Science*, p. 45.)

A.D. 1840.—Smee's galvanic battery was invented in 1840. In this single-fluid arrangement the elements are, platinized silver, dilute sulphuric acid, and amalgamated zinc. (See Smee's *Electro-metallurgy*, p. 18; also Gmelin's *Handbook of Chemistry*, p. 419.)

A.D. 1840.—Mason, in 1840, employed the battery process in electrotypy. (See *Proceedings of the Electrical Society*, April 1840, p. 203; also Walker's *Electrotype Manipulation*, part I., p. 22.)

A.D. 1840.—Mr. Andrew Crosse, in 1840, imitated constant and intermittent springs, by passing the current from a constant galvanic battery through moistened pipe-clay in a garden-pot placed in a basin full of water. (See Noad's *Manual of Electricity*, pp. 390-392.)

A.D. 1840.—M. De Ruolz, on December 19, 1840, took out a patent [in France?] for electro-gilding. He uses the following solutions:—The double chloride of gold and sodium dissolved in soda, chloride of gold dissolved in yellow ferrocyanide of potassium, sulphuret of gold dissolved in neutral sulphuret of potassium. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 549-551.)

A.D. 1841.—M. Abria, in 1841, proved that, in magnetizing a steel needle by an electro-dynamic helix, whatever be the length of the needle, provided it is not longer than the helix, its poles are always

placed at the two extremities of the part inserted, and that the portion which is outside the helix is not magnetized. He also investigated the influences that the length and diameter of the needles, and the length and diameter of the helix, exerted over the magnetic intensity, and found that the longer a needle or helix was in comparison to its diameter, the greater the magnetic intensity. (See De la Rive's *Treatise on Electricity*, Vol. I., pp. 287-289; also Vol. II., p. 889.)

A.D. 1841.—M. De Ruolz, in 1841, electro-deposited brass from the cyanides of zinc and copper dissolved together in a solution of cyanide of potassium. (See Gore's *Theory and Practice of Electro-deposition*, p. 62; also Walker's *Electrotype Manipulation*, last edition.)

A.D. 1841.—Professor Grove, in 1841, read a paper at a meeting of the London Electrical Society, in which he proposed to etch daguerreotypes by the voltaic current. The solution used consists of moderately dilute hydrochloric acid. (See *Practical Mechanic and Engineers' Magazine*, October, 1841, p. 34; also Smee's *Electro-metallurgy*, p. 336.)

A.D. 1841.—Mr. Alfred Smee, in 1841, published the results of his electro-metallurgical experiments, and enunciated the laws regulating the character of the metallic deposit. He electro-deposited the following metals from their solutions in the reguline form:—Platinum, gold, palladium, iridium, rhodium, silver, nickel, copper, zinc, cadmium, iron, lead, and antimony. Many applications of electro-metallurgy are set forth and suggested in the three editions of Smee's "Electro-metallurgy." (See Smee's *Elements of Electro-metallurgy*, 1st edition, 8vo., London, 1841; also the 2nd and 3rd editions of the same work.)

A.D. 1842.—Professor Morse, in 1842, gave it as his opinion that Europe and America might be connected by means of the electric telegraph. (See Whitehouse's pamphlet, *The Atlantic Telegraph*, pp. 3, 4.)

A.D. 1842.—Mr. J. P. Joule, in 1842, made some remarkable researches on the electric origin of the heat of combustion. (See *British Association Report*, 1842, p. 31.)

A.D. 1842.—Bunsen's double-fluid galvanic battery was invented in 1842. Its elements are, coke, nitric acid, dilute sulphuric acid, and amalgamated zinc; a hollow cylinder of coke is made to surround a rod of amalgamated zinc. Bonijol places a hollow cylinder of zinc round a solid cylinder of coke. (See Gmelin's *Handbook of Chemistry*, pp. 392 and 423; also De la Rive's *Treatise on Electricity*, Vol. I., pp. 45-47.)

A.D. 1842.—Grove's gas battery was invented in 1842. This arrangement consists of platinized platinum plates arranged in pairs, one plate of each pair being in contact with oxygen gas and acidulated water, the other in contact with hydrogen and the same acidulated water; the pairs are connected as in ordinary galvanic batteries, and the gases are absorbed during the action of the battery. (See De la Rive's *Treatise on Electricity*, Vol. II., pp. 723, 733.)

A.D. 1842.—MM. Masson and Bréguet, in 1842, constructed an electro-dynamic coil, with which they obtained a spark between the poles in vacuo without previous contact, the apparatus being in connection with a galvanic battery. (See Noad's *Manual of Electricity*, pp. 726, 727.)

A.D. 1842.—Mr. Robert Davidson, in September, 1842, tried his electro-magnetic locomotive upon the Edinburgh and Glasgow Railway. It consisted of horseshoe electro-magnets opposed radially to keepers fixed on the driving wheel shafts parallel to their axes. Mr. Davidson was engaged in the construction of electro-magnetic engines in 1837. (See *Practical Mechanic and Engineers' Magazine*, November, 1842, pp. 49-52.)

A.D. 1842.—Roberts' single-fluid galvanic battery, and the method of using it for blasting purposes, were made public in 1842. The battery consists of cast iron and amalgamated zinc plates placed interlacing in a frame; the exciting liquid is dilute sulphuric acid. The whole apparatus for blasting consists of the battery, conducting wires, cartridges, and galvanometer to test the cartridges; the conducting wires are insulated from one another, and twisted so as to form one rope; they terminate in the cartridge, and have fine steel "balance wire" stretched across their ends; their other terminations are connected to the battery poles. To use this apparatus the cartridge is placed in the centre of the charge of powder, and the battery connection made, when the steel wire becomes red hot, fires the cartridge, and explodes the charge of powder. (See *Practical Mechanic and Engineers' Magazine*, November, 1842, pp. 45-48.)

A.D. 1842.—M. Matteucci, in 1842, wrote upon the electric current proper to the frog, and determined the condition of its development and its course. (See *British and Foreign Medico-Chirurgical Review*, January, 1854, pp. 134-137.)

A.D. 1842.—Wöhler and Weber, in 1842, used a double-fluid galvanic battery, in which iron was the positive as well as the negative plate; the positive plate was immersed in dilute and sulphuric acid, the negative plate in strong nitric acid, and thus kept in a passive state. (See *Annalen de Chemie und Pharmacie*, Vol. XXXVIII, p. 307; also Gmelin's *Handbook of Chemistry*, Vol. I., p. 423.)

A.D. 1842.—Moser, in 1842, discovered that if two bodies are in contact, or very near together, they impress their image upon each other. Karsten succeeded, a short time after Moser's discovery, in producing similar figures under analagous circumstances, making use of frictional electricity. A glass plate, placed between a coin and metal plate, which respectively receives and conveys away the electric fluid, has the image of the coin. This image appears, in its most minute details, on being breathed upon. (See De la Rive's *Treatise on Electricity*, Vol. II., pp. 174-180.)

A.D. 1843.—Mr. Cubitt planned the destruction of the Round Down Cliff by electro-blasting. This event took place January 26, 1843. (See Noad's *Lectures on Electricity*, pp. 191-193.)

A.D. 1843.—M. Dubois Reymond, in January, 1843, announced the following law of animal electricity (the so-called "frog current"):—"When any point of the longitudinal section of a muscle is connected by a conductor with any point of the transverse section, an electric current is established, which is directed in the muscle from the transverse to the longitudinal section." (See *British and Foreign Medico-Chirurgical Review*, January, 1854, p. 137.)

A.D. 1843.—Mr. J. P. Joule made public his galvanometer in 1843. This instrument consists of a pivoted magnetic needle, which can be surrounded by coils respectively adapted to the measurement of the galvanic current under examination. (See *Practical Mechanic and Engineers' Magazine*, October, 1843, pp. 39, 40.)

A.D. 1843.—MM. Bréguet and Konstantinoff, in 1843, constructed a chronoscope depending on the same principle as that of Professor Wheatstone; a rotating cylinder with styles is, however, substituted for the clock movement. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 138, 139, and 150; also De la Rive's *Treatise on Electricity*, Vol. III., pp. 484, 485.)

A.D. 1843.—Professor Wheatstone, in 1843, proposed to register observations of meteorological instruments. The electric circuit is completed by the contact of mercury with a platinum wire placed in the tube of the instrument. In this way the meteorological condition of space may be observed by means of a balloon, or the instruments may be buried in the depths of the earth. The "thermometer telegraph" is said, in a Report addressed to the British Association, to act perfectly at the distance of many miles. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 128-132.)

A.D. 1843.—Mr. Nott, on August 17, 1843, read a description of his rheo-electric machine to the British Association. It consists of a plate of glass and a plate of resin; the rubbers to these plates being connected, "a complete circle is formed, as in the voltaic pile." (See *Practical Mechanic and Engineers' Magazine*, September, 1843, pp. 469, 470.)

A.D. 1843.—Mr. G. Little, in 1843, described an "electro-magnetic motion." A metallic ball is caused to move in a circular metallic railway by the alternate tipping of the sole plate; the rails are divided at opposite points of the circle, and caused to complete the electric circuit differently, according to the position of the ball on one or other semicircle; the tipping of the sole plate is caused by horseshoe electro-magnets alternately excited by the above-described means. (See *Practical Mechanic and Engineers' Magazine*, August, 1843, pp. 435, 436.)

A.D. 1844.—Baron Reichenbach, in 1844, investigated the action of electrical forces of all kinds upon "sensitives," and found that electrified bodies appeared to the "sensitives," in an absolutely dark room, to give forth luminous emanations. Other effects are described. (See Reichenbach's *Researches on Magnetism, Electricity, Heat, Light, Crystallization, and Chemical Attraction, in their relation to Vital Force*. Translated and edited by Dr. Gregory, London, 1846.)

A.D. 1844.—Mr. George Little, in 1844, described an "electro-locomotive." It consists of an axle on which T-shaped magnets are placed; fixed horseshoe electro-magnets act upon these, and, by means of a commutator, produce rotation of the axle. (See *Practical Mechanic and Engineers' Magazine*, May, 1844, p. 290.)

A.D. 1844.—M. Pouillet, about the year 1844, invented a chronoscope, having for its principle the deviation produced by a given battery upon a given galvanometer by various durations of completion of the galvanic circuit. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 132-138; also De la Rive's *Treatise on Electricity*, Vol. III., pp. 485-486.)

A.D. 1844.—Mr. John Dancer's electro-metallurgical experiments were not published till 1844, although they were made about the year 1838. Metallic copper was deposited on sheet copper with a letter D, cut from a printed bill, fastened on to it by varnish. An electro-cast of a stamp on a copper cylinder was also obtained. (See *Mechanics' Magazine*, February 3, 1844, pp. 76, 77.)

A.D. 1845.—Schoenbein, in 1845, wrote upon ozone at the request of the British Association. This odorous principle is produced during the action of the electrical machine, manifested in thunder-clouds, developed in the electrolysis of water, and appears always to attend electric polarization. (See *Report of the British Association* for the meeting in 1845, p. 91; also De la Rive's *Treatise on Electricity*, Vol. II., pp. 469-480.)

A.D. 1845.—M. Heider, in 1845, employed a platinum wire, heated by a voltaic battery, to cauterize the dental nerves. (See De la Rive's *Treatise on Electricity*, Vol. III., p. 687.)

A.D. 1845.—Professor William Thomson, in 1845, showed how the electric polarization is to be taken into account in the Leyden jar. (See *Encyclopædia Britannica*, 8th edition, art. Electricity, p. 534.)

A.D. 1845.—Mr. C. V. Walker, in 1845, by means of three Daniell's cells and a brass anode, electro-deposited brass from a strong solution of cyanide of potassium, which had been sequentially electrolysed with a copper and zinc anode. Alloys of gold and copper, or gold and silver, may be electro-deposited by similar means. (See *British Association Report* for the meeting in 1845, p. 30.)

TELEGRAPHY AT THE BRITISH ASSOCIATION.

By Amicus.

Every unprejudiced individual will, doubtless, admit that electrical science, and its attendant, submarine telegraphic science, cut but a sorry figure at the meeting of the British Association. It is somewhat remarkable, but the illustrious presidents of these gatherings have pretty well something to say on every department of science, except this. One will speculate on the probable exhaustion of our coal-fields some two or three centuries hence, in proportion as we are economical or otherwise. Another takes us back to such remote periods as to really stagger us with the hazy distance; pre-Adamite, we may, certainly, call them, but somewhat in the same sense that we should term Rameses the Second the predecessor of Queen Victoria, or the Antediluvians as antecedent to this present generation. To read the history of the formation of our world upon the rocks, and trace its gradual development through myriads of centuries; to speculate upon the antiquity of man; and to set staid orthodox people by the ears at the apparent upsetting of the Mosaic record of the creation, are doubtless noble employments for one's time and faculties. And certain it is that it furnishes not only many columns, but many volumes, for the curious, far more interesting to some people than mere dissection of human motives and character, and the vivid or sensational pourtrayals of the seething passions that boil in the bosoms of modern bipeds. Sir Charles Lyell gave us a spice of almost everything, and as Bath was supposed to be an uncommonly ancient place, salubrious withal, having five mineral springs, and so forth, and patronized in times past by the upper ten thousand pretty considerably, of course he went into the subject rather, and exploded a few notions anent its antiquity, much to the chagrin of some of the natives. But from Bath we went to the ends of the earth, and had a taste of geography, geology, ethnology, and all the rest, but not a word of anything respecting the advance of telegraphic science. Why, sirs, here is a science of more vital importance to mankind, and the British empire in particular, than all the ologies put together. It is assumed that the president will take us a tour through all the sciences in his opening address; it is, however, unreasonable to expect him to do so. But if this session, just brought to a close, had been called a meeting for the association of scientific speculations, with just a *leetle* bit of mechanical speculation thrown in by way of variety, it would have been more aptly termed. The president set the example, by as thorough a speculating address as ever delighted an audience of profundities, and it is but justice to say that the example thus set was well followed up.

To wit, what was there of advancement denoted in the three papers read touching electrical and telegraphic science? Literally nothing.

First came Captain Selwyn, with a paper on "Submarine Telegraphy," a manifest misnomer, however, since it was the old dish warmed up afresh, which has already done service at the Inventors' Institute, and elsewhere. Nothing new had the captain to relate, unless it be that Mr. John Macintosh is the happy individual who has discovered the palladium which is to settle the battle of the insulators, henceforth and for ever. With respect to his own invention, it cannot be called new now, seeing the gallant captain has been straining every nerve these two years past to get it adopted. It is a good idea, doubtless, but that is not the point; and seeing it is not adopted we must call it a new old thing. No disrespect, however, is intended; it ought to be tried like a good many more things whose existence is ignored. Captain Selwyn's ideas of what would constitute a good cable, in respect of mechanical construction, are somewhat novel, and he can only lay claim to any practical knowledge of the subject from what he conceives would meet the requirements of the case nautically. There are, however, two, if no more, sides to this question. Still the views advanced were only a new edition of the same put forth at the Society of Arts, and other places, some time ago, so that this part of his paper was but a recapitulation of *what ought to be*, and might very well have been dispensed with. The man who made the first cotton reel was a benefactor to his species, as much so, perhaps, as the immortal unknown who made the first road; indeed, if it should so turn out that a long deep-sea cable cannot be successfully laid except by means of a huge reel, it will become a matter of doubt whether the former were not the greater man of the two, and, in that case, we shall unquestionably award Captain Selwyn the full meed of praise, and may he grow corpulent in more substantial proceeds. He loves his progeny, as a good parent should. Take, therefore, Mr. Thomas Allan's conductor, Mr. John Macintosh's insulator, make them into a cable, on the heart of oak principle, carefully eschewing any external covering, whether for protection or destruction, then add Captain Selwyn's cylinder, or, rather, add the cable on to the cylinder, as Clark does his cotton, and you are all right. Here is your cable and means of submersion all as simple and straightforward as the first three letters we learn in our primers. Let this prospect rejoice your hearts, ye poor demented ones, who have paid so dearly, in experimental lessons, of "how not to do it." Rejoice in the existence of the above triumvirate, who, without a doubt, will put "a girdle round the earth in forty minutes." Is there nothing new here? Let us hasten to revoke the rash expression made above. It *is new;* there's no mistake about it; but how unfortunate it should be all speculative. There are those ingrate, blind bats and moles, that they are, who put no faith in Mr. Allan, nor in Mr. Macintosh, nor yet in Captain Selwyn. Alas that it should be so! And alas! and alas! for the splendid dreams of one who erst had detailed so clearly to Earl Derby, K.C.B., &c., and his colleagues, how the four continents of this planet, and all the isles of the main might, by his principle of telegraphy, be banded together in one glorious confederacy, by a network of electrical communication, producing order, happiness, and harmony, like the golden cords that hold countless suns and myriad spheres in their unerring course; a dream worthy to be realised. But the man is something more than a dreamer, and deserves better of his country.

Next comes Mr. Fairbairn, "On the Mechanical Properties of the Atlantic Cable," and this paper, although speculative in the highest degree, is about the greatest novelty extant. Here is a man, perhaps the greatest recognised authority on mechanics, who has written some of the most useful and popular books thereupon in the English or any other language, whose utterances are oracular, and who merits and receives, in mechanical affairs, the trust and confidence of the mechanical community, and whose practical abilities have earned for him a wide-spread fame, and a host of letters to the end of his name—yet here is a man tacitly delivering a laudatory address on the "mechanical properties" of a cable, the very construction of which sets at nought some of the plainest mechanical laws. Well, well, shall we use the hackneyed phrase and say, "truth is stranger than fiction!" Extremes meet, and many a wise man errs. No, no, it was quite right "not to leave the cable to chance;" and yet it looks very much as if "chance" or something not much better had had to do with it. We must necessarily infer that the jade had a pretty considerable hand in the first, but she must have set a tolerable copy, seeing the second

is so much like it, being, in fact, a second edition, enlarged, and (shall we say?) revised. Mr. Fairbairn, like Captain Selwyn, very carefully enters into the minutest descriptive details of the construction of a cable, with which the public are already sufficiently posted up, therefore there can be nothing new, and decidedly no advancement is denoted of telegraphic science, except *in prospectu*, and that is necessarily speculative, if not problematical, so far as this design is concerned. But its High Priest is far too sensible a man to be sanguinely prophetical of the result. He confines himself mainly to the, in his view, reasonable grounds there are for anticipation that it *will be* a success; it is to be feared, however, that these will be considered of little worth by most people. The novelty of this paper consists in certain assertions which one would have thought so careful a man would studiously avoid making. For instance, it was necessary, as it were, to make some remarks respecting the insulation, as a sort of half apology for the adoption of precisely the same description of dielectric used in its ill-fated predecessor; since some people (whether justly or not, it doth not behove us to inquire) attributed its failure, in a great measure, to the defectiveness of the material used as a coating for the conductor. In justifying, therefore, the joint use of gutta-percha and Chatterton's compound, it is asserted "that although caoutchouc is a more perfect insulator than gutta-percha, the latter is the more durable." With unthatched deference let us ask, how does Mr. Fairbairn know this? True it is rolled as a sweet morsel under the tongue of those who, naturally enough, wish to keep a formidable rival out of the field; but it is a cuckoo cry, nevertheless, and has not a tittle of foundation in fact; it is so much the more to be deplored, therefore, that this eminent mechanician, and practical philosopher, should allow himself to be made the echo of monopolists. This gentleman, however, seems to be in blissful ignorance of his inconsistency as a mechanic. "The covering wires (of iron) constitute the principal strength of the cable." Indeed! "The convolutions of a spiral never elongate." Oh! dear no! And consequently no strain can fall upon the only longitudinal portion, namely, the core and its frail conductor! Of course iron does not rust in water, and, if it did, how is it possible to supervene when carefully embedded in "Manilla yarn, saturated with a preservative compound!" The protector of a protector! Imagine Oliver Cromwell wanting his wife to take care of him! Captain Selwyn had spoken of the invention of Mr. John Macintosh as the *ne plus ultra* of perfect insulation, but strange to say this material is not only not adopted in the manufacture of the most important cable that will, in all probability, ever be required, but there is no allusion made to it, and the contest seems to have lain between gutta-percha and india-rubber, and the former gained it. So much for Mr. Fairbairn's contribution to the advancement of speculative mechanical science, with assumptions, contradictions, and inconsistencies, to the session of 1864.

The paper read by Mr. Thompson, "On the Mechanical Theory and Application of the Laws of Magnetic Induction of Electricity," is of a very different description. May the Fates keep us from getting out of depth here! What an absurd idea to suppose that the charge of a thunder-clap does not weigh so many ounces avoirdupois! Will anybody write to that marvellous man, the editor of *Notes and Queries*, and inquire the exact weight of the electricity used in telegraphing Her Majesty's Speech of last February to the Imperial Lord of the Tuilleries? But if electricity were a ponderable fluid it could not be induced, therefore don't trouble the erudite gentleman with any questions, the answer seems to be "nil," and the charge of the aforesaid cloud is force (in a form?). If "heat be internal excitation of motion in matter," and "light the excitation of motion in a rare medium called æther," since "they are not matter, but force in act," why, it necessarily follows that electricity and magnetism are not matter, but different developments or forms of force, "which may either be in conatus or in act." Hence "electric conduction is molecular movements of particular portions of matter, and "magnetic conduction is the symmetrical arrangement, into a vortical sphere of spirals, of a general medium, which pervades all matter and holds it in that form for the time being;" and of course we all know how these different forms of force are excited. Well, here was a new theory, at any rate, for the sages at the mineral springs to cogitate over, but, novel as it is, it seemed to drop almost still-born in their midst; there was no discussion, or next to none; and yet, doubtless, there were men present who had not given up the undulating theory of light, and a good many other old-fashioned theories, so esteemed by our author. But this theory was to lead to a practical result. Mr. Thompson is, if not an inventor, at least an ingenious adapter of something like an amplified Ruhmkorf coil, whereby five cells of Daniell are made to do the work of 100 cells of the same in an ordinary voltaic battery, a result, by the way, well worthy the consideration of all electricians and telegraph engineers, and is hereby specially recommended to the consideration of the magnates in Telegraph-street.

But the question arises, are the advantages gained by doing away with 95 per cent. of battery power with all the accumulated dirt, trouble, consumption of zinc, water by local action, and all the rest of the inconveniences consequent on a large series of elements, sufficient to compensate for the wear and tear of a series of connected induction coils, whose whole capacities are taxed to the utmost in order to make the five cells, as generators of the induced charge, equal to the 100 cells without the coils? In other words, is there any pecuniary gain? Competent judges say there is not. Ordinary induction coils only give a spark as the machine makes and breaks contact; but Mr. Thompson claims to produce a continuous stream of electricity by his arrangement, and that it is non-intermittent. If it be so, he certainly has accomplished something. But here again good judges are at issue with him, and declare absolute non-intermittence to be an impossibility. Certainly, if it be intermittent, the contrivance is comparatively useless for signalling purposes. But the great test of its use or worthlessness will depend upon its adaptability to the requirements of long lengths of submarine cable. A good authority, the late Dr. Esselbach, says that a spark even cannot be obtained where there is not perfect insulation; and perfectness of insulation is simply impossible in submarine lines, whether the dielectric be gutta-percha, india-rubber, or Mr. John Macintosh's preparation of paraffin. There is always a degree of induction to be overcome—an obstacle with which a charge of induced electricity by Mr. Thompson's contrivance would be simply unable to cope: at least, such is the general opinion. In order to establish the mechanical soundness of his arrangement or invention, Mr. Thompson began by the promulgation of a theory which overturns remorselessly the prevailing ideas of light and heat, and necessarily of electricity and magnetism also; but it is merely speculative, and far from being established; and even if it were, it is difficult to see how telegraphic or any other science is advanced or benefited by it. The electro-magnetic induction machine is a clever contrivance, but it remains to be seen if it really be worthy to supersede the ordinary mode of generating electricity for telegraph and other purposes. And if it should turn out to be all that he claims for it, the advantages even then are not such as to justify the author in claiming the having advanced electrical science to any appreciable degree. It was unfortunate for Mr. Thompson that he could not speak *ex cathedra*, for then all the smell-funguses of Germany would have been down on him on the light and heat theory, and he would have been a great man. Who would have cared about Colenso and the Pentateuch if he had not been a bishop?

THE EMBRAYAGE ELECTRIQUE.

At a recent meeting of the Association of Foremen Engineers, Mr. Gettliffe read a paper on "An Apparatus for the Prevention of Steam Boiler Explosions and Railway Accidents." That gentleman, after some preliminary observations, proceeded to say that the apparatus in question was the invention of M. Auguste Achard, C.E., of Paris, and that it was known in France under the title of the "Embrayage Electrique." It was calculated to maintain a constant level in steam boilers by automatic means, and without the assistance or supervision of the engine-man. This regulator, as it might be termed, consisted of a rachet wheel of peculiar construction, and which was keyed, upon a spindle turning freely in its bearings. Right and left of the wheel were mounted, loosely on the spindle, two wrought-iron levers of about twenty inches each in length, and connected together by cross-pieces. A two-armed "click," supported by the levers, turned freely round an axis. The double click acted freely upon the ratchet wheel, which was furnished with two sets of teeth, turned in opposite directions to each other, and separated by a blank space. The click was fitted with a tail-piece in the form of a fork, the two prongs of which were braced together by a cross-rod. In the fork was mounted an "armature," which was provided with an opening through which passed the cross-piece. The armature was made of brass, and to it was attached a plate of soft iron fitted in so as to be flush with the surface of the armature. Opposite to this latter was placed a horizontal electro-magnet, the poles of which abutted against the armature in such a way as that it (the armature) could only slide against the poles, without coming into immediate contact therewith. The part played by the armature was merely to act as a weight on the levers supporting the fork; for it would be understood that when the electric current was in circulation, the armature would be suspended by its adherence to the electro-magnet, and thus relieve the fork of its weight. The

suspension of the current, on the contrary, would cause it to drop on the cross-piece connecting the levers, and thus alter the gravity of the fork. It was these alternations of the weight on the tail-piece of the levers which caused the fork to act upon the upper or lower set of teeth on the ratchet-wheel; or, in other words, to open or shut the feed-cock of the boiler. It was necessary that the fork should have continual motion—a kind of pump-handle movement indeed—which could be effected by a simple contrivance (a small eccentric, for instance, attached to a running shaft on the general machinery). The effect would be that the compound rachet wheel would be acted upon and moved in one direction when the boiler required feeding, and in the other when it had been fed sufficiently. If all were going on well, the click would be simply moved over the blank portion of the wheel, and communicate no motion whatever to it. Proceeding now to the general action of the contrivance, the reader proceeded to state that when the current was broken off from the electro-magnet, the weight of the armature operating upon the cross-piece would press down the tail-piece of the levers carrying the click, which latter would rise and act with its lower arm upon the rachet wheel. The consequence would be, that the wheel would turn from left to right to the extent of one tooth, or about half-an-inch, at each oscillation of the levers, until the blank space presented itself and stopped further movement. This would be at a point when the wheel had made one-fourth of a revolution. On the other hand, when the current was in circulation, the armature, in sliding against the poles of the electro-magnet, would bring the plate of soft iron into contact with the poles, which would then hold it firmly, and prevent the armature descending with the click during the downward oscillation of the levers. The tail-piece would thus be relieved, and not have to support any weight while the levers rocked in the opposite direction. It would follow that the upper arm would then act upon the wheel, and cause it to turn the reverse way, *i.e.*, from right to left. It would thus become evident that the two-armed click would act on the rachet wheel, and cause it to move in opposite directions, whether the electric current were traversing the electro-magnet or not. "Now," said the reader, "the characteristic feature of the electric regulating apparatus is arrived at." The rising or falling of the float in the boilers of stationary or land engines controls the electric current, and causes it to circulate or be interrupted at the proper times. This result is obtained directly by the wires which proceed from the pile or battery being made to pass first to the float, instead of being connected immediately to the electro-magnet. The float itself was connected by a rod with an index, on the lever of which was mounted a piece of wood, faced on one side with a brass plate. On another piece of wood, in the form of a rocking lever, and moving on an axis, was a second plate of brass. The electric wire from one of the poles of the battery was fixed to the first-named plate, and the other end of the wire, after traversing the electro-magnet, was attached to the other pole of the battery. In order that the current might circulate, it was indispensable that both plates should meet, and, from the peculiar arrangement of the two metallic plates, they would always be in contact when the index was at zero (the normal feeding point) or above it, but the contact ceased as soon as the index fell below zero. Let it be supposed that the feed-cock of the force-pump, or other contrivance for supplying water to the boiler, was connected to the spindle of the ratchet wheel; it would follow that the cock must partake of the movement of the wheel, and that it will make a quarter of a turn in one direction when the electric current circulated, and a quarter of a turn in the other when the current was interrupted. Thus the automaton regulator, which was sensitive to the smallest alteration in the water level of the boiler, was perpetually and inevitably maintaining it at a constant height, and thus one great source of danger was obviated. As an extra security, however, against accident by explosion, a minor contrivance was affixed to the same apparatus, and which owed its action to similar principles. On the side of one of the levers was fastened a cap with a gudgeon in its centre. An armature resembling that already described was carried by this cap and rested on the gudgeon. In connection with the second armature was placed an electro-magnet, against which it was made to slide and press constantly upon the poles. It was still the index of the water gauge, which induced the circulation or effected the interruption of the electric current; and the same electric pile or battery, composed of a single element, or Daniell's pair, sufficed to put in motion the two electro-magnets. The electric wire which proceeded from one of the poles of the battery, and was affixed to the brass plate on the lever of the index, served for the two electro-magnets also. The returning wire, corresponding with that about to be described, however, was fixed to a third brass plate, and, after traversing the electro-magnet, was attached to the second pole of the battery. The last-mentioned plate was arranged in such a manner as to establish a metallic contact, which permitted the electric current to pass, notwithstanding the variation in the level of the water to the extent of an inch above or below its proper line. If the variation exceeded these limits, the current would be forcibly broken. When the electric current was in circulation—that is to say, when the lever was between the limits of variation named—the armature would be suspended by the adhesion of the second electro-magnet, but, if the level rose or fell beyond those points, the armature, from the current being broken, must fall. In either case, a small tappet fixed to the armature below the gudgeon touches an alarm lever and thus rings a bell. This arrangement was also serviceable in other respects. The alarm bell rings when the feed pump is out of order, when the electric pile ceases to act, if the stoker neglects the fire, or if steam is generated too rapidly. The reader proceeded to point out the application of the "Embrayage Electrique" to the prevention of railway accidents, by connecting it with brakes upon the wheels of the engines and carriages, and certainly gave some very practical illustrations of its value and efficacy in this respect. In France it is extensively used, and testimonials in its favour from many eminent scientific men were submitted to the Associated Foremen Engineers. Mr. Gettliffe, moreover, exhibited the apparatus itself to his audience, and thus gave them a further opportunity of judging of its characteristics.

ANNUAL REPORT BY CHAS. TODD, Esq., SUPERINTENDENT OF TELEGRAPHS, &c., SOUTH AUSTRALIA, 1863.

(*Continued from page* 155.)

RECEIPTS AND EXPENDITURE.

The number of messages, it will be seen, has increased from 76,725 in 1862 to 86,411 in 1863; and the net revenue from £7,677 5s. 8d. in the former year to £8,429 19s. 1d. in the latter. The total value of messages in each year was respectively £11,801 3s. 7d. and £13,120 16s. 7d., being an increase of £1,319 13s. 0d.

Compared with the previous year, the receipts show an increase at the following stations:—Adelaide, Port Adelaide, Peninsula, Gawler, Clare, Glenelg, Nairne, Woodside, Strathalbyn, Port Elliot, and M'Grath's Flat; and a decrease at Kapunda, Auburn, Burra, Mount Barker, Willunga, Goolwa, Guichen Bay, Mount Gambier, and Penola.

At Kapunda and Auburn, although the receipts were less than in 1862, the actual amount of business was more. The only serious falling off was at Guichen Bay, where the receipts fell from £318 19s. 0d. in 1862 to £211 2s. 9d. in 1863; and at Penola, where they declined from £200 11s. 9d. in 1862 to £149 12s. 3d. in 1863. The receipts at Mount Gambier have steadily decreased since 1861, owing to a portion of the business being transferred to M'Donnell Bay, and to the fewer land sales in the immediate district.

The total expenditure, exclusive of new lines, was £9,968 18s. 10d., of which £8,798 0s. 1d. was the proportion charged to working expenses and maintenance of lines, or, adding the rent of the chief office (£310), £9,108 0s. 1d., a sum exceeding the net revenue by £678 1s. 7d., a fact to be accounted for by the number of unremunerative country stations.

The expenditure for the maintenance and repairs of lines was unusually large owing to the heavy gales and long continued rains of the winter, which of course told severely upon every weak pole. For convenience in comparing the operations of the past with former years, I have given in the following table the revenue of each station during the last four years:—

Table showing Receipts at every Station during the Four Years 1860, 1861, 1862, 1863.

Station.	Total Receipts.											
	1860.			1861.			1862.			1863.		
	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.

	7,414	9	4	7,382	9	8	8,047	7	7	8,695	0	1

Dividing the stations into two classes, paying and non-paying, the former comprises the following:—Adelaide, Port Adelaide, Gawler, Kapunda, Clare, Burra, Kadina, Wallaroo, Port Elliot, Robe, Mount Gambier, Penola, and M'Donnell Bay; and the latter—Peninsula, Auburn, Glenelg, Mount Barker, Nairne, Woodside, Gumeracka, Strathalbyn, Willunga, Goolwa, and M'Grath's Flat. The Yankalilla, Wellington, and Kincraig offices just about pay their expenses.

It is, however, too early to expect the telegraph to yield any profit; its real value, as I have before remarked, consists, not so much in the actual amount of revenue which it yields, but rather in the aid which it affords to commercial enterprise, the administration of justice, and the rapid settlement of the country through which it extends; regarded in this light, it far more than pays for the outlay incurred in its construction and maintenance.

CENTRAL OFFICE.

Pending the final decision of the Government as to the site for the central office, arrangements have been made with Messrs. Green & Wadham for an extended occupation of the present premises for another year, and I have made such alterations as will meet our immediate requirements. The whole of the lines are brought into one office at night, which enables me to economize my staff, and great improvements have also been made in the battery cellars.

LINES IN OTHER COLONIES.

For the following information relative to the progress of the telegraph in Victoria I am indebted to the valuable report of Mr. M'Gowan, detailing the operations of his department up to the end of 1862. His report for last year has not yet reached me.

In 1862 provision was made for the following works, the estimated cost of which was £34,250, viz.—Removal to, and erection of, lines along the routes of the railway between Geelong and Ballaarat, and between Melbourne and Sandhurst (including special provision of a distinct wire for railway service); a second (intercolonial) wire between Albury, New South Wales, and Mount Gambier, South Australia; a branch line from Ballaarat to Smythesdale; a line from Avoca to Red Bank; an extension of the Inglewood line to Swan Hill.

In 1863 provision was made for further extensions, viz.—1. A line connecting Melbourne with Sale and Port Albert (Gipps Land). 2. A branch line from Castlemaine to Newstead. 3. A branch line from Hexham to Mortlake. Besides alterations and improvements to existing lines, amounting to £7,500, making in all an estimated expenditure of £18,500.

The second intercolonial wire from Melbourne to South Australia was completed in the first half of 1863, and the communication on the Victorian side will shortly be further secured from interruption by a cross line from Hexham to Hamilton, now in course of construction. This will provide two independent lines between Melbourne and Portland, thus—one line direct to Portland, viâ Geelong, Colac, Camperdown, Warrnambool, and Belfast; and one viâ Geelong, Ballaarat, Beaufort, Streatham, Hexham, Hamilton, and Portland. From Portland the two wires are continued to the South Australian border on the same poles, which have been, I believe, renewed throughout.

Our communication with Melbourne and Sydney has been greatly improved since the completion of the second wire in Victoria. We are now able, as a rule, to work direct with Melbourne, thus saving the necessity for repeating at Mount Gambier; and in cases of long reports we can, if we wish, work with Sydney, a circuit of 1,300 miles.

Mr. M'Gowan proposes a system of telegraphic communication between the different public offices in Melbourne, which are very much scattered. Wheatstone's alphabetical instrument, of which twenty-six have been ordered from England, are to be used, and Siemens and Halske's india-rubber covered wire will be employed for connecting the offices.

Through the kindness of Mr. Cracknell, who introduced Professor Wheatstone's instrument on the railway lines in New South Wales, I had lately an opportunity of trying them here. They are exceedingly simple, and require but little or no experience to work them, and answer very well in short simple circuits with only two instruments, but not where there is much resistance. I have also imported two of Henley's magnetic alphabetical instruments. In these a much more powerful current is obtained; but, except in very practised hands, it is almost impossible to avoid tripping, or to produce the proper number of electrical pulsations to work the escapement. If the handle is started or stopped slowly, the index needles do not start or stop simultaneously; and it is exceedingly difficult, when working quickly, to stop the current at the proper letter without "slowing." This is effected very neatly in Wheatstone's instrument by means of the key-board; and if this could be combined with Henley's arrangement, I think we should have a serviceable alphabetical instrument.

In 1862 the receipts of the Victorian department were £26,834 19s. 8d. on 162,647 messages. The working expenses of the department were £33,340 2s. 3d., showing a loss on the year of £6,505 2s. 7d.; but Government telegrams are not included in the foregoing statement, as they are not paid for in Victoria; they numbered 49,038 messages, valued at £15,446 0s. 9d., thus making the total earnings of the department £42,281 0s. 5d. The free transmission of service telegrams, by inducing an extravagant use of the telegraph, is, in my opinion, a very serious evil and inconvenience to the public, whose private messages are thereby frequently delayed.

There were 78 stations open in Victoria, with 1,975¼ miles of line in operation, during the year 1862.

In New South Wales, under the able management of Mr. Cracknell—who, it will be remembered, came out with me—the telegraph is making most rapid strides, and contrasts favourably with the other colonies in yielding, so early in its history, a net profit on the outlay of from 6 per cent. in 1861 to 7¾ per cent. in 1862.

The total capital invested in telegraphic extensions, including £12,222 8s. 1d. for stations, up to the end of 1862, was £116,234 11s. 7d.

	£	s.	d.
The revenue in 1862 was	25,513	9	8
The working expenses	16,780	7	5
Profit	£8,733	2	3

The following statement shows the increasing utility of the department:—

				£	s.	d.
1860—Number of messages	53,951	Receipts		12,136	13	2
1861 „ „	74,224	„		16,542	8	9
1862 „ „	104,660	„		25,513	9	8

The following statement, showing the extensions completed since 1860 and their total cost, will be useful:—

Since Captain Martindale's report to September, 1860, the following new lines and stations have been opened:—

From Gundagai to Kiandra—98 miles in length; contract price, £50 per mile, and £25 per mile for 22 miles of wire on existing poles, which were erected as guide poles; cost, exclusive of stations, £4,726 4s. 4d. Stations opened—Tumut, 11th March, 1861; Kiandra, 16th October, 1860.

From Bathurst to Orange—35 miles; contract price per mile, £45 10s.; total cost, £1,730 11s. 11d. Orange station opened 21st December, 1860.

From Bathurst to Mudgee—length of line, 91 miles; contract price per mile, £44; total cost, exclusive of stations, £5,887 7s. 7d. Mudgee station opened 16th May, 1861; Sofala, 15th May, 1861; Windeyer, 6th August, 1862; Tambaroora, 3rd October, 1862.

From Gundagai to Deniliquin, viâ Wagga Wagga—length, 220 miles; contract price per mile, £46, and for a wire on existing poles from Gundagai to Tarcutta, 35 miles, at £16 10s. per mile. Wagga Wagga station opened 10th June, 1861; Deniliquin, 1st August, 1861; and Urana, 29th October, 1861.

On the 1st August, 1861, the line from Deniliquin to Moama, 51 miles, was purchased from the Deniliquin Telegraph Company at a cost of £2,820 8s., being 10 per cent. advance on the original outlay.

The completion of the above line to Deniliquin, and the purchase of the latter portion from the company, supply two distinct routes between Gundagai and Melbourne, a result which has proved of great advantage when interruptions have occurred on the direct line viâ Albury.

The next extension of importance is from Maitland to the Queensland boundary at Maryland, viâ Singleton, Muswellbrook, Scone, Murrurundi, Tamworth, Bendemeer, Armidale, Glen Innes, and Tenterfield; length, 375 miles; contract price, first section, from Maitland to Murrurundi, 100 miles, £46 per mile; second section, from Murrurundi to the boundary, 275 miles, £48 5s. per mile; total cost, £21,354 15s. 10d.

The stations were opened on the following dates:—Singleton, 25th February, 1861; Muswellbrook, 11th June, 1861; Murrurundi, 12th June, 1861; Tamworth, 10th October, 1861; Armidale, 14th October, 1861; Glen Innes, 20th December, 1861; Tenterfield, 8th November, 1861; and through communication to Brisbane was established on the 9th November, 1861.

From Goulburn to Braidwood—51 miles; contract price per mile, £41; total cost, £2,494 15s. Braidwood station opened 25th November, 1861.

From Campbelltown to Wollongong and Kiama—58 miles; contract price per mile, £38; total cost, £2,830 8s. 2d. Wollongong station opened 11th August, 1862; Kiama, 15th October, 1862.

From Mudgee to Wellington—48¼ miles; contract price per mile, £43; total cost, £2,505 19s. 10d. Wellington station opened 12th September, 1862.

From Grafton to Tenterfield—112 miles; contract price per mile, £39; total cost, £4,570 14s. 11d. Grafton station opened 17th December, 1862.

From Orange to Wagga Wagga, viâ Forbes (the Lachlan gold-fields), and (Young) Burrangong—225 miles; contract price per mile, £43. Forbes station opened 27th October, 1862.

This line is drawing near completion, and when opened through to Wagga Wagga will form a second and distinct means of communication with Victoria, viâ Echuca, and Sandhurst, so that only under extraordinary circumstances can an interruption between the two colonies occur, and which will render prolonged delays, from the crowded state of the lines, less frequent.

A second wire, between Muswellbrook and Scone, has also been provided for, to be worked by Wheatstone's alphabetical instruments. Contract price per mile, £20; total cost, £303 8s. 6d. The Scone station was opened 10th May, 1862.

PROPOSED EXTENSIONS FOR 1863.

A line from Deniliquin to Hay, an estimated distance of 80 miles. From Braidwood to Queanbeyan, 35 miles. From Wellington to Dubbo, 35 miles. An additional wire from Sydney to Newcastle.

Tenders have been received for the above lines at the undermentioned rates:—Deniliquin to Hay, £43 per mile. Braidwood to Queanbeyan, £37 per mile. Wellington to Dubbo, £41 10s. per mile.

These extensions have been guaranteed by the inhabitants of the districts they are intended to connect, that they will be responsible for the annual

payment of 5 per cent. (return by the lines) on the capital invested, after paying the working expenses.

In 1862 there were 2,174 miles of line, and 2,539 miles of wire at work in New South Wales, connecting 47 stations. In 1863 stations were opened at Hargraves, on the Mudgee branch, and East Maitland, on the north line; and Hay, Dabbo, and Queanbeyan will be opened shortly, making 2,344 miles of line at work.

In Queensland there are 200 miles of lines in operation, and new lines to Rockhampton and Port Denison are in progress.

At the end of 1863 the Australian colonies had about 5,521 miles of line, 6,850 miles of wire, and 175 telegraph offices, all erected in a little more than eight years.

TELEGRAPHIC COMMUNICATION WITH EUROPE.

It does not seem probable that any steps towards the realization of this project will be taken until we have had some experience of the working of the Euphrates Valley and Persian Gulf line to India, as it would clearly be premature to enter into any engagements for the Australian section before the communication between England and India has been completed and proved reliable; the present year will probably determine this. In the meantime, the Queensland lines are being pushed on to Port Denison, a loan of £85,000 having been authorized for that purpose; and the line from thence could easily be extended to the Gulf of Carpentaria, or to our new northern settlements near the Adelaide River, should the direct route from South Australia be for the present abandoned. There can, however, be little or no doubt that the latter will be ultimately carried out, if only to serve the purpose of an alternative line.

In my letter of the 27th December last, I have recommended that the Government should deal directly with the manufacturers of the cable, who should have the whole responsibility of laying it, and keeping it in good working order for the first year; or the cable might—perhaps with advantage—be leased to the manufacturers under suitable arrangements. The Malta and Alexandria cable is so leased from the Home Government by Messrs. Glass, Elliot, & Co., who made it; the term expires on the 1st January, 1867. The lessees have to keep the whole line in efficient repair, the land line and shore ends of the cable solely at their own expense, and in the event of any other portion of the cable becoming defective it is, if necessary, to be replaced by new cable, in all respects as good as the original cable when first laid, the Government providing the ships required for that purpose. Messrs. Glass, Elliot, & Co. also work the land line between Alexandria and Suez, under an arrangement for four years with the Telegraph to India Company, paying a rental to the latter of £2,500 per annum. The Telegraph to India Company purpose at once extending their lines from Cairo to El Arish, and thence to Beyrout, a distance of 400 miles, at an estimated cost of £20,000; from which point they contemplate its future extension to meet the Persian Gulf and Constantinople line near Diabecker, which will thus afford additional security against interruption west of the Euphrates Valley.

With regard to the submarine section of the Java-Australian line, it has been generally supposed that the depths would seldom exceed 50 fathoms, and that the nature of the bottom is favourable. No detailed soundings, however, appear to have been made between the east end of Java and for about 60 miles beyond Timor; but I learn from a valuable paper on the Submarine Plateaus between Asia and Australia, contributed to the *Journal of the Indian Archipelago*, by George Windsor Earl, Esq., M.R.A.S., that between the Asiatic and the Australian banks of soundings there exists a volcanic gorge, the narrowest part of which is between Timor, on the northern verge of the Australian bank of soundings, and Kalatoa, on the southern verge of the Asiatic Plateau, where it is about 180 miles across. Its depth cannot be ascertained by the ordinary sounding apparatus, owing, perhaps, to the strong current from the eastward; but Mr. Earl thinks it possibly does not exceed 1,000 fathoms. As the cable must cross the gorge, careful soundings will therefore have to be made. The bottom of both plateaus are favourable for the preservation of the cable, consisting mainly of clayey mud mixed with sand and shells, which is soft under water, but when exposed to the air becomes exceedingly hard. On neither plateau has any trace of volcanic action yet been discovered; but Mr. Earl states that "all the islands of the Indian Archipelago, which are not included within the submarine plateaus defined above, are of volcanic origin, and the greater number of the larger islands contain volcanoes in a state of activity at the present time." The course which Mr. Earl, from his knowledge of those seas, recommends the cable should follow is from East Java, along the Asiatic Plateau, "to its extremity near Kalatoa, where it crosses a gap 60 miles in width to the Iron Cape of Flores. This gap has never yet been sounded; but the depth is not likely to be very great, nor are the surface currents strong. The track then passes the Gut of Larantuka, a small Portuguese settlement, where the soundings vary from 13 to 50 fathoms, over a rocky bottom. On leaving the Gut, a second gap has to be crossed, nearly 90 miles in width, and through which the current sets to the south-west, almost without intermission, at a velocity near the surface of one mile and a half to three miles an hour, which, however, is very considerably less than the rate at which it rushes between Ombay and Timor." From Timor to the Australian coast there would be no difficulty or danger.

OBSERVATORY AND METEOROLOGICAL DEPARTMENT.

Meteorological observations have been continued at the different stations named in my report for 1861. The results for 1862 have been printed, and those for last year are in an advanced state. The instruments ordered for the lighthouses have arrived, and will be mounted as soon as I can arrange to visit the several localities.

Daily weather reports are exchanged with the other colonies, and I have recently arranged with Mr. M'Gowan and Mr. Ellery, the directors of the Williamstown Observatory, for a regular system of warning signals round the coast on the appearance of approaching bad weather.

I have recommended provision being made on the estimates for the erection of an elevated look-out and flag-staff at the Normanville Telegraph-office, by means of which vessels arriving from the eastward may be signalled much sooner than at present.

I have also recommended provision being made for a time-ball at the LeFevre's Peninsula Station, which I propose should be dropped by signal from the Observatory at one p.m. Adelaide time. The ball is to be sufficiently elevated to be seen at the port, as well as at the anchorage outside.—I have the honour to be, &c., CHARLES TODD,

Observer and Superintendent of Telegraphs.

The Hon. the Commissioner of Public Works.

CORRESPONDENCE.

PAPERS ON TELEGRAPHY READ AT THE MEETING OF THE BRITISH ASSOCIATION, HELD AT BATH.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—There are some material errors in the abstract report of a paper read by me before the British Association, "On Submarine Telegraphy," which I hope you will allow me to correct; and the discussion on Mr. Fairbairn's paper, "On the Mechanical Construction of the Atlantic Cable," as well as on my own, I regard as so important to the interests of telegraphic science, that I trust you will not deem any apology necessary for my giving you a more full account of them than that published in the local papers.

First, with regard to Mr. Fairbairn's paper, Captain Galton distinctly stated in the discussion that he for one did not consider the so-called consulting committee responsible for the mechanical construction of the Atlantic cable, now being put into the Great Eastern; nor was it such an one as they would have recommended on any other than financial considerations. Secondly, Mr. Fairbairn thoroughly acknowledged that the spiral outer wires could not in any way give increased tensile strength, particularly if the cable were allowed to revolve; and he also said that they, the scientific committee, had tried to remedy the faults of the cable submitted to them, but did not consider it to be the best possible. There was a table of figures exhibited, which showed the breaking strain, but not the diameter, or any other conditions of each of the cables submitted by different makers; and Mr. Fairbairn acknowledged that this table was not comparative, nor could anything be learnt from it, except that one maker's cable of an inch and an eighth diameter was stronger than another's of five-eighths of an inch; stronger, that is, in air, and of those sizes, for no comparison was made of the lengths of themselves they would support in water, if of equal external diameter. One would fain hope that the proximate result of all this will be the abandonment of those outer spirals which have really been the "arms of death" to too many unfortunate but well-insulated wires.

I now pass to my own paper, and, first, I complain that I am made to say, "I tell you engineers." I hope I never wrote or spoke such a presumptuous piece of folly. What I did write was, "We seamen tell you engineers," after guarding myself by also writing, "I claim only to be heard as the mouthpiece of my profession." Now this is very different, if not in the matter, yet in the manner, and I hope your readers will give me credit accordingly. The next error I have to observe upon is one affecting the size of the cylinder. I never was so foolish as to propose a cylinder of 22,000 tons burden to carry a cable which only weighs *in air* under 6,000 tons, even if I ever had advocated the employment of one cylinder instead of two, which I have not done. Two cylinders, each in tow of its separate ship, or two ships, offer always the advantage of halving the time necessary for the operation, for as they proceed together to mid ocean, and there commence laying, it is clear that only six or seven days, instead of twelve or fourteen, will be required for the two ends to reach shore. In the case of the Great Eastern, this advantage is necessarily given up.

I only mentioned a cylinder of 120 feet long by 90 in diameter as giving the tonnage of the Great Eastern* (22,000 tons), by way of showing those who fancy that a cylinder to carry as much cable must necessarily be as large as the ship, what a serious error they commit. The size of each of two cylinders, which would have been necessary to take the place of the Great Eastern in laying such a cable as the present Atlantic—say 2,500 miles of 35 cwt. to the mile in air, and $1\frac{1}{8}$th in diameter—would be 60 in diameter and 75 long, having a tonnage each of 6,057.

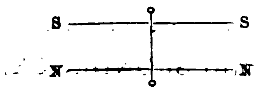
The arguments which I adduced in favour of the use of cylinders were so fully admitted, and my views on the subject of wave motion, as affecting the laying of cables were so strongly confirmed by almost all of the scientific men who spoke during a discussion which lasted two hours, that on this subject I have only to hope that the time is considerably nearer when the

* The beam of the Great Eastern is 83 feet, and her length 690; over paddle-boxes breadth is 114 feet.

system I have so long advocated will receive a fair trial; but I was pleased to notice that Mr. Allan's cable is also receiving a very greatly-increased portion of its well-merited commendation, and that there is no discouragement on account of the failures in submarine telegraphy, so marked as to amount to a mistrust of the future of this essential means of progress in the too long-delayed telegraphic union of the nations.

I had the pleasure of showing at the Bath meeting two interesting facts in electricity and magnetism, of which I shall soon be ready to give you a more detailed description. The first is a printing telegraph, the property of M. Delaye Lepaul, of Paris, which prints through a single wire in Roman characters at a speed of thirty words per minute. Any child who can spell can send by it. It is not liable to trip, and can be adapted as well to electro-magnetic as to voltaic currents. You may take out or replace thirty miles of resistance without any error being thereby caused, and nothing but ordinary printers' ink is employed.

The second is a magnetic curiosity in the shape of astatic needles joined as usual by an aluminium bar, the upper one of which has apparently no north pole, and the lower no south pole, thus—



These behave most curiously under the action of the galvanic current, as might have been expected, owing probably to the composition of the forces brought into play. It is a discovery of my own, which may possibly be of some value in the construction of future instruments, or in other magnetic research.

For the purpose of showing the action of a voltaic current on these needles, I used a new form of battery, which I strongly recommend to your student readers. It is thus formed:—Take a strip of copper, say twelve inches long and two wide; sew it up in linen, after passing through two holes a bit of copper wire for the terminal, which is soldered into its place. Roll it up into a helix with a piece of thick zinc (the ordinary thick zinc plate of commerce); this to be half an inch wider, and also to have its terminal similarly affixed. Put a little mercury in the bottom of an earthen or glass jar, and insert the two spirals. Fill up with acidulated water, and you will have a self-amalgamating constant battery cell of very little internal resistance, very cheap, very clean, and easily put in or out of action, its quantity being almost the greatest possible in the space. I have had the cell in action on short circuit through a galvanometer for two months, with only a change from 70° to 65°. The water was changed by an india-rubber syringe, which sucked it out and put in fresh—at the end of the first month very little sulphate of zinc showing itself. If not wanted, it is put out of action by lifting the two spirals out together, and putting them to drain on the top of the cell. Yours, &c.,

J. H. Selwyn, Capt. R.N.

A LESSON ON LEGISLATIVE AND EXECUTIVE FUNCTIONS.

To the Editor of the Telegraphic Journal.

Sir,—We are obliged by your insertion of our note of the 17th inst., and also for your comments thereon. There is some asperity in them, but, perhaps, the tone of our note induced it.

We demur to your dictum that Directors are "honorary officers." The Directors *issue* directions, and the officers *receive* directions. Confusion frequently arises from the line between legislative and executive functions not being kept clearly in view, and responsibility ceases to fall on the proper shoulders in consequence.

Our admirable British Constitution offers a ready and apt analogy. The shareholders represent the constituents, the Directors are the Legislature, and the officers the Executive. The highest officers of state are only "Secretaries of State," and the Prime Minister himself is but "First Servant" (in plain English) of the Legislature.

If you open your columns to remarks upon this subject, you will, we think, receive many interesting communications.

We are, sir, your obedient servant,

Universal Private Telegraph Co., Lewis C. Hertslet, Sec.
London, 26th September, 1864. Nath. J. Holmes.

TELEGRAPHIC NEWS.

Malta and Alexandria Telegraph.—On the 26th ultimo a telegram was received by Messrs. Glass, Elliot, & Co., announcing the re-opening of the Malta and Alexandria telegraph for the transmission of messages to Egypt, India, China, Australia, &c.

The Atlantic Telegraph.—Mr. C. W. Field, the original projector of this great enterprise, was in Pictou, Nova Scotia, on the 20th of August, and was the guest of Major Norton, the American consul, by whom he was hospitably entertained. Among the guests present were the editors of the *St. John's News* and *Globe*; Mr. Hoyt, the manager of the Nova Scotia telegraph line; and other gentlemen. The evening passed very pleasantly, the company listening with much pleasure to the statements made by Mr. Field relative to the proposed laying of the cable.—*Canadian News.*

A New Company.—We learn that the Messrs. Crossley, of Halifax, the great carpet manufacturers, are about to transfer their extensive business and premises to a company (limited), with a proposed capital of £1,650,000, in 110,000 shares of £15 each, of which it is intended to call up not more than £10 per share. We note this fact as Mr. L. J. Crossley has for many years evinced a great interest in telegraphic pursuits.

The New Telegraph Cable to Fortress Monroe.—A submarine telegraph cable of English manufacture has arrived at Fortress Monroe. It is to be laid across the Chesapeake Bay from Fortress Monroe to Cherrystone. The old cable has been useless for several weeks.—*American Artizan.*

Alarming Fire at the Telegraph Offices in Threadneedle-street.—About eleven o'clock on Monday night, the 26th ultimo, a serious fire occurred at the City terminus of the Submarine Telegraph Company and the British and Irish Magnetic Telegraph Company, Threadneedle-street, City. At that time smoke was observed to be issuing from the roof, and soon afterwards flames broke forth from a room on the fourth floor, which was filled with stationery and stores to the value of £500, belonging to the Submarine Telegraph Company, and contiguous to a room filled with their instruments, connected with Continental wires. The room had only been closed for a few hours when the fire was discovered. The night clerks on duty made an effort to extinguish the fire by running up a length of hose fixed to a hydrant on the second floor landing; but the force of water was so feeble that it dropped short of the fire. On the arrival of the firemen a delay of ten minutes occurred before water could be procured from the New River Company's mains, but when the engines were got into work the flames were prevented from descending to the lower part of the building, but the Baltic wine stores, which were on the basement, were a good deal damaged by water. The following letters have been received from the several offices, from which we learn that the damage is not so serious as was at first supposed:—"Sir,—I am instructed to inform you that a fire broke out about eleven o'clock last night in this building, which has destroyed this company's instrument-room and instruments, and consequently has occasioned some delay in the transmission of messages. However, through the kindness of other telegraph companies in lending us instruments, we were enabled to re-establish the direct communication with Paris and Brussels at an early hour to-day, and we trust that in the course of to-morrow all our lines in connection with the Continent will be in working order, so that messages will be transmitted and received as usual. It is satisfactory to state that the property destroyed is amply covered by insurance.—I am, Sir, your obedient servant, S. M. Clare, Secretary.—Submarine Telegraph Company, 58, Threadneedle-street, E.C., Sept. 27." "Sir,—I beg to inform you that the fire which took place at this station last night has not in any way interfered with the communication to the Continent, or to any station in the United Kingdom. Messages are accepted and despatched as usual.—By order, J. Newbury, Station-master.—British and Irish Magnetic Telegraph Company, Central Station, Sept. 27."

Military Telegraphs.—The Select Ordnance Committee, recently appointed by the Admiralty and the War Department to inspect and report upon the improved systems of day and night telegraphing in military and naval operations, combined or independently of each other, have returned to town from the Isle of Wight. They have completed their labours, with the exception of the official presentation of their report. The committee arrived at Portsmouth on Tuesday, the 20th ultimo, from London, and, embarking on board Her Majesty's paddle steamer Pigmy, Master Commander Vine, left the same afternoon for Ventnor, Isle of Wight, where they landed, accompanied by Captain Bolton and Commander Colomb. They proceeded thence to the signal station on St. Catherine's Down, near Black-gang Chine. It was to be made the head-quarters of the committee during their stay in the island, and become also the signalling head-quarters during the intended exposition of the results of Captain Bolton's and Commander Colomb's labours for the information of the committee. The signal station on St. Catherine's Down was under the command of Captain Bolton, and was furnished with the Holmes magneto-electric light and Captain Bolton's field lime-light, as supplied to the telegraphic corps of the Royal Engineers for night signalling, and a Venetian blind shutter apparatus and a set of naval code flags for day signalling. Two men of the Royal Engineer telegraphic corps formed Captain Bolton's staff. Ashy Down, 7½ miles inland from St. Catherine's Down, was another appointed station on the island, and one of the field lime-lights for night signalling, with a double collapsing cone for day signalling, were stationed there in charge of two men of the Royal Engineers. At the semaphore tower in Portsmouth Dockyard, 14¾ miles from St. Catherine's Down, was placed a non-commissioned officer of the Royal Engineers with two signalmen, in charge of a field lime-light for night signalling. Her Majesty's steamer Pigmy was in charge of Commander Colomb, in positions out seaward as required, and was fitted with one of the magneto-electric lights (of the same description and power as the one on St. Catherine's Down), a field lime-light, and a flashing apparatus for night signalling; a double collapsing cone and a steam jet for day signalling. In the *Telegraphic Journal* we gave a general description of the magneto-electric and lime-lights, and the means of day signalling by the cone, shutters, and steam jets. It is therefore only necessary on this occasion to draw attention to the fact that Captain Bolton and Commander Colomb's system of signalling may be said to be based on the "Morse" systems of telegraphy, the long and short dashes in the printing of the "Morse" telegraphic message being efficiently and simply represented

in the Colomb-Bolton system by the length of time in which the double collapsing cone, Venetian shutters, or any other dark object is exhibited by day, or by the length of time in which the magneto-electric and field lime-lights on shore, or the plain flashed lamp at sea, are exhibited by night. Colours are totally discarded in these signals, for the reason that a plain white light by night will transmit its message to a much greater distance than any coloured light possibly can do, at the same time that the apparatus is simplified by the use of one kind of light only to a *minimum* point; and a dark opaque object, such as the collapsing cone or shutter apparatus, is preferable, for the same reasons, to coloured flags by day. The steam-jet signals remain to be noticed. The efficiency of this mode of communication from a vessel at sea to a headland on the coast was discovered in a very curious manner. One day during the recent experiments which have been carried out between Captain Bolton, on St. Catherine's Down, and Commander Colomb, on board the Pigmy out at sea, communication from the Pigmy became very difficult owing to the distance from the land and the peculiar state of the atmosphere. The hull of the Pigmy could just be discovered at sea from the Down; but it was quite impossible to distinguish masts or yards, and therefore equally impossible to read any signal by the cone. While she was being watched as she lay thus by Captain Bolton and his party on the Down, three or four white dashes (thrown off steam) of different lengths stood out most prominently over the steamer's hull, against the dark horizon in the background. These white dashes, or escaped lengths of steam, furnished the hint for the steam-jet signal. A steam vessel lying so far off from the land that, like the Pigmy, her ordinary mode of day signalling would be useless can, by throwing off jets of steam, print off her message in long and short dashes against the darker background over the horizon as certainly and as legibly as the electric instrument on shore prints off its dots and dashes on its paper riband or tape. On Wednesday morning, the day succeeding the arrival of the committee at St. Catherine's, they were employed in discussing the reports handed in by Captain Bolton and Commander Colomb, with which they expressed the greatest satisfaction. On the afternoon of the same day Her Majesty's ship Pigmy proceeded to sea, and when four miles off St. Catherine's commenced steaming out slowly from off the land and signalling to the committee on St. Catherine's Down with ordinary naval flags. At six miles and a half distance the flags failed altogether, being then at too great a distance to be distinguishable from the Down, and signalling was then commenced with the flashing system, the shutter apparatus, the double collapsing cone, and steam jets. It was kept up for some time at an average distance of seven miles, and always at a greater speed than that gained by naval flags at one-third the distance. On Wednesday evening night signalling was commenced between the Down and the Pigmy, twelve miles at sea, with the lime-light, and was continued at a great speed up to fourteen miles distance, when the magneto-electric light was brought into play, and continued the signalling up to seventeen miles. Messages were also forwarded direct to Portsmouth Dockyard, and answers received in return, and also to the station on Ahsy Down; but the most interesting portion of the signalling was between the bold headland of St. Catherine's and the Pigmy, out in the Channel. On Thursday the committee were employed in carrying out experiments in field signals with Captains Bolton and Colomb's apparatus, and rapid communication was kept up at will, by day and by night, between two moving parties two miles distant from each other. This concluded the experiments, and the committee expressed their warm approval with all that had been submitted to them for examination. It is understood that immediate measures will now be taken, on the recommendation of the committee, to introduce permanently the combined Colomb-Bolton system into the army and navy as the signal code for both services in all future operations by land or by sea, whether singly or in conjunction with each other.

MISCELLANEA.

£600 Reward.—The proprietors of one of our contemporaries advertise that they will give £600 reward to any one who will catch a director asleep on a railway, and frighten him into a belief that the safety of his throat and pocket are threatened, so that he may come to practical conclusions as to the necessity for communication between the traveller and guard.

The Saving of Life by Railway Travelling.—A writer in a recent number of the *Revue des Deux Mondes* computes the average yearly loss of life on railway journeys as 1 in 7,000,000 travellers whereas 70,000 in 30,000,000 travellers would be no more than the fair proportion to the annual loss of life in former days among travellers by land and sea.

The Production of Sulphur in Italy.—During the last ten years great improvements have been introduced in the method of extracting sulphur from calcareous gangue. It is always obtained by liquefaction by burning a portion of the ore; but this operation, formerly performed in small open cylindrical furnaces (*calcarelle*), is now effected by simply heaping the stones and covering them with earth, as in the process of charcoal burning. The sulphur at present produced in Italy amounts to no less than 800,000 tons a year, the value of which in the rough state is 30,000,000 francs. This yield, which has increased ten-fold since 1830, is furnished in great part by Sicily. The quantity produced in Romagna, formerly but small, has since increased to 8,000 tons per annum.

Increased Explosiveness of Mining Powder.—Mr. Nobel announces that by damping mining powder with nitro-glycerine its explosive power is trebled, and the noise of the explosion much less than when ordinary powder is used.

Electricity in Combination with Gas.—The insidious element of electricity is being applied as a motive power, and may some day, not very remote, outstrip even the wonderful achievements of steam. By its great power we speak from continent to continent, and space becomes annihilated. Who can say that it will not yet become the greatest and most useful agent ever known? Already we find the principle being illustrated, in combination with gas, in the Lenoir Gas Engine. The inventive genius of the times has grasped the idea; its development will be sure to follow.—*American Gaslight Journal and Mining Reporter.*

Silvering.—Cold silvering may be performed on brass and copper which is well cleaned and quite bright, by rubbing with a moistened cloth, dipped in the following powder:—1. Chloride of silver, 2 parts, pearlash, 6 parts, salt, 3 parts, whiting, 2 parts; mix. Or, 2. Precipitated silver, 1 part, common salt and cream of tartar, each 2 parts; mix. When the metal is silvered, it should be washed in a hot weak solution of alkali, and then washed dry. Other silvering powders are:—3. Nitrate of silver and salt, of each 1 part, cream of tartar, 7 parts. 4. Nitrate of silver, 1 part, cyanide of potassium, 3 parts. 5. Bath: Nitrate of silver, 15 parts, sulphate of soda, 100 parts; dissolve in water, and dip the article into the solution.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2307. C. W. Howell, improved means or apparatus for communicating from the passengers or driver to the guard of a railway train.
2312. F. Hovenden, improvements in railway signal apparatus.
2341. A. V. Newton, improvements in the mode of and machinery for manufacturing telegraphic cables.—A communication.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2047. T. P. Tregaskis, the improved use of magnets in overbalancing weights.
2127. J. Packer, improvements in signals in railway trains.
2158. A. M. J. Count de Molin, an improved electro-magnetic engine.
2182. W. J. Curtis, improvements in railway carriages and in the means to be employed by passengers in signalling to the guards of railway trains.
2217. H. W. Cook, improvements in electric telegraphs.—A communication.

PATENTS WHICH HAVE BECOME VOID.

2292. F. Barnett, improved automatic electric signals to prevent collisions on railroads and railways.
2298. T. M. R. Weare, and E. H. C. Moncton, improvements in batteries for obtaining electric currents and the products therefrom.
2303. J. Reeves, improvement in electro-magnetic engines for obtaining and applying motive power.
2310. R. A. Brooman, improvements in apparatus for stretching, supporting, and uniting telegraph wires.—A communication.
2411. I. L. Pulvermacher, improvements in apparatuses for creating electric currents, chiefly for medical purposes.

NOTICE TO PROCEED.

1223. E. W. Farrell, improvements in the method of and apparatus for communicating between the guard and the engine-drivers of railway trains.

PRICES CURRENT OF INSULATING MATERIAL.

Gutta Percha, as imported.

Genuine, fine and good	2/2 to 2/6	per lb.

DOMESTIC TELEGRAPHS.

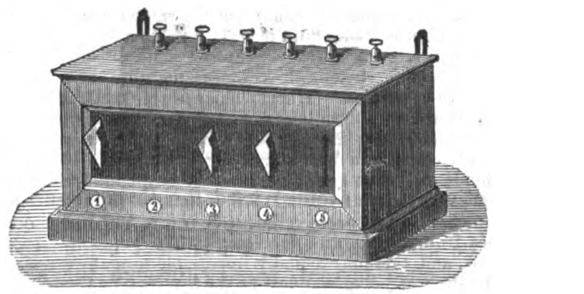
Some few weeks since the attention of the public and the readers of this journal was called to the employment of electricity for domestic purposes, in an essay by Mr. W. H. Preece, Assoc. Inst., C.E.

The remarks made by the author, showing the great superiority, in every respect, of the electric over the mechanical method of hanging household bells, induced Mr. Francis Wyatt Truscott, of the firm of Truscott, Son, & Simmons, the printers and publishers of this journal, to apply the new system to his residence, 5, Park-crescent, Portland-place.

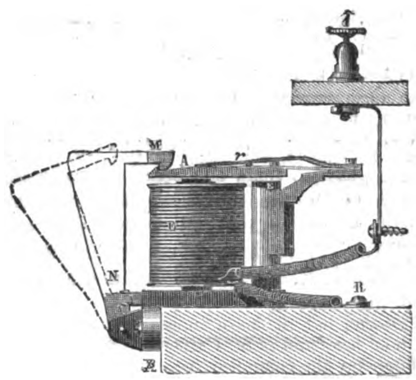
Great difficulty is always experienced in introducing novel and untried systems into use in this country. Prejudices have to be overcome, fears dissipated, and confidence secured. The purest logic may prove the new thing to be perfect and faultless, but unless the questions "Where is it at work?" "Who has used it?" can be satisfactorily answered, the persevering introducer has to meet with nothing but shakes of the head and shrugs of the shoulders. The greatest anxiety may be evinced for its welfare; every satisfaction may be expressed with its practicability; but no one will venture to undertake the responsibility of being the first to adopt it for practical use. How George Stephenson had to hammer railways into the thick heads of Parliamentary Committees! and how Cooke had to sigh for years before he could secure assistance to introduce his telegraph! So with the application of electricity to domestic purposes. Many have expressed their approval of the principle, but few have cared to incur the risk of success or failure in its introduction to English homes and English hearths. Mr. Truscott has prominently stepped forward and taken upon himself the responsibility of introducing the electric system into general use in England, and too much credit cannot be given to him for raising himself above those petty prejudices which invariably surround projectors and their novelties.

Mr. Truscott has had his house completely fitted up with the new system. Its superiority over the old arrangement is most apparent. The ease and freedom with which the buttons are pressed—the slightest pressure being sufficient to sound the bell without the necessity of exerting that violent pull which distinguishes the old bell-crank—the tranquillity and noiselessness with which the power circulates through the wire—the absence of all disfigurements to the walls and passages—and the simplicity with which the different rooms are distinguished—not only render this system a vast improvement upon existing plans, but prove it to be an elegant scientific principle.

As a description of the work carried out may be interesting to our readers, we append, from personal observation, the following remarks. The system selected by Mr. Truscott is that known in France as "Bréguet's." Immediately outside the servants' hall are placed the indicator and the bell. The indicator is fixed four feet from the ground, and the bell immediately above it. The indicator (whose general appearance corresponds with the following sketch, only that instead of having five



indices as shown, it possesses sixteen, in two rows of eight each, each index corresponding to a room, and having the name of the room painted above it,) is placed low, to enable the servant to restore the indices to their normal position as soon as he has responded to its call. The interior construction of the indicator and its action are shown in the following sketch. When a current of electricity, generated by the pres-



sure of a button in any particular room, passes through the electro-magnet (E), the armature (A) is attracted, and the metal piece (M N) falls by its own gravity, as shown by the dotted lines, and appears through a slot in the ebony front of the indicator. 1, 3, 4 indices are shown as having been depressed in the first figure. These indices are painted white to render them more visible. They are restored to their normal position by pressing them back with the finger.

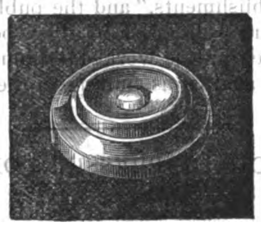
The same current that releases the pointer rings the bell, which is an ordinary trembling bell, as fully described in Mr. Preece's paper. One bell thus acts for every room in the house, and the particular room that rings is distinguished by its pointer on the indicator.

The battery is placed in a cupboard near the indicator, and is the ordinary sulphate battery.

The wires, insulated with a thin layer of india-rubber and covered with a protecting coating, are carried from floor to floor up a wood shooting, and branch into each room between the joists and beneath the flooring.

The terminal wire of the indicator is connected, through the bell, with one terminal of the battery; the other terminal is carried, by a wire, upstairs, with a branch to the buttons or pulls in each room, dining, breakfast, library, billiard, drawing, bed-rooms, &c., to the top of the house. From each "button," or "bell-pull," a second wire is carried direct to the indicator, connected to the terminal corresponding with the name of the room. In several of the rooms many buttons are

fixed (for instance, in the drawing-room there are *four*); these are simply branches from the main one.



The buttons (see sketch) used are those described in Mr. Preece's paper, and consist simply of a rubbing contact. It can thus be easily seen that, on contact being made in any room, the electric current, passing through the button, steals noiselessly along the wire to the indicator, passes through the electro-magnet, and, attracting the armature, exposes the indicating piece, rings the bell,—calling the servant's attention—and returns to the other pole of the battery.

On the servant hearing the bell he will immediately see, from the indicator, whose attendance is required, and in what room; and before attending to the summons he will restore the indicator to its normal state, by simply pressing back the weight until it is caught by the armature. In the bed-rooms and bath-room, in addition to the ordinary "button," a silk cord, containing wires with a spring contact at the end, is fixed, this being used in bed or in any spot where it would be difficult for any one to touch a button.

Besides the communication between the rooms upstairs and the servants' hall, separate communications are made from the hall and the drawing-room landing to the nursery and servants' rooms, and also from the best bed-room to the nursery.

Everything acts in the most satisfactory way, and great credit is due for the manner in which the work has been carried out. We believe it was completed under the superintendence of Mr. G. E. Preece, whose name is well known to the readers of this journal.

ERRORS IN TELEGRAPHIC MESSAGES.

In scientific investigations, in chemical manipulations, in commercial transactions,—indeed, in all terrestrial affairs, if we except the giving of evidence in a court of justice by an "active and intelligent officer," human kind evince a liability to error. If we project railways, and a speculative mania ensues, involving thousands in ruin; if we build a leviathan ship, and, on its completion, are unable to get it off the stocks; if we manufacture a telegraph cable to connect the Old with the New World, and sink it in mid ocean, useless, except as a plaything for the monsters of the deep,—a great outcry is raised, and somebody is found to be at fault. Englishmen will exercise their prerogative of grumbling, and sometimes find an occasion to improve in the telegraph service. Complaints of inaccuracy are now and again preferred against telegraph clerks, whose business is of an important, though critical character, when contrasted with ordinary mundane operations. To account for these murmurings, and to indicate where the evil sought to be remedied not unfrequently originates, are the objects of the following remarks. Manuscript is often tendered to signallers which would puzzle an expert to decipher, and the bearer of the despatch is found to be as uninformed of the nature of its contents as was Diogenes of the velocity of light. There is no time for enquiry or reference, off the telegram must go, as accurate as practicable under the circumstances. On reaching the nearest station to its destination, the bulletin is again liable to misadventure. The code of signals employed (as the Morse instrument has now found its way on to most European lines) is sometimes open to mis-interpretation, owing to the similarity of words, the approximate identity of characters, and the absence of stops in most messages.

Of probable mistakes on lines where the practice of reading by sound is adopted, Mr. Todd, superintendent of telegraphs in South Australia, thus speaks:—"Many errors occur in the rendering of words having a similarity of sound, such as 'to' for 'two;' 'for' for 'four,' &c.; and from the code signals of two different words closely resembling each other unless sent carefully; for example, in one instance the word 'tons' (— — — — — · · · ·) was substituted for 'kegs' (— · — · — — · · · ·), the operator transmitting the word thus (— · · · · · · — · · ·). 'Meet' (— — · · —) is likely to be read 'get' (— — · · —)." "In India," says Sir W. B. O'Shaughnessy Brooke, "the errors are chiefly in numbers, 'six' for 'sixty,' 'fifteen' for 'fifty,' and the like. Names of places and persons, especially of natives; 'purchase' for 'purchased,' 'insure' for 'insured,' 'ship' for 'shipped,' 'about' for 'above,' 'bales' for 'sales;' 90 mistakes in every 100, arising from the confusion of similar sounds in words of different meaning, or the omission of a letter or a syllable."

Another class of errors is well illustrated by the following order received by a London merchant, to ship "forty tons of *fog* to the Mediterranean." This novel cargo was manufactured from the abbreviations usually accompanying an order to deliver goods *free on board*, the initial letter b (— · · ·) in the last word, having been rendered g (— — ·), by the phenomenon known as the retardation of electrical signals. "Your wife has a fine *boy* this morning," was intended to intimate the birth of a son; the letter x (— · · —) being very similar to y (— · — —). "Don't come—too late," was a message once sent from Edinburgh to a medical gentleman in London, but, being delivered without the pause, it read "Don't come too late," upon which he started off, and only found out the fact that in telegraphy punctuation is ignored, after having performed a wearying journey of 400 miles. Mistakes of this kind are not so frequent now as formerly, as a more skilful class of manipulators preside at the stations. Receiving (and here we speak professionally) a message is not so simple a matter as many people imagine. To decipher dashes and dots, made on a paper tape, or to translate from the dictation of a machine, and to write in a legible hand the utterances of the electrical automaton, is an art only to be acquired by many years of patient application. That instances of gross neglect and culpable stupidity do occur on the part of signallers, we are fain to admit; but they are the exception to a commendable rule. An amusing anecdote is related, by Mr. Prescott, of an American gentleman who sent a despatch to parties in New York, requesting them to "forward sample forks by express." When the message was delivered, it read thus:—"Forward sample for K. S., &c." The parties who received the despatch replied by asking what samples K. S. wanted. Of course the gentleman came to the office and complained that the message had been transmitted wrong, and the operator promised to repeat it. Accordingly he telegraphed the New York operator that the despatch should have read, "Forward sample forks." The New York operator, having read the telegram wrong in the first instance, could not decipher it differently now. He replied that he did read it "sample for K. S.," and so delivered it. "But," returned the Boston operator, "I did not say 'for K. S.,' but 'f-o-r-k-s!'" "What a stupid that fellow is in Boston," exclaimed the New York operator, in a rage, "He says he didn't say 'for K. S.,' but 'for K. S.!'" The Boston operator tried for an hour to make the New York operator read it "forks," but, not succeeding, he wrote the despatch on a piece of paper and forwarded it by the mail, and it remained a standing joke upon the line for many months afterwards.

The data on which our knowledge concerning errors in telegraphy is based is of a local character, yet sufficiently com-

prehensive to show that the telegraphic operators have, in a few years, attained a very extraordinary degree of accuracy. It is difficult to obtain reliable information as to the internal economy of English telegraph lines, because they are in the hands of private individuals, who preserve records of their default, but who are very chary in publishing them to the world, lest they should evoke adverse criticism. Well, there may be a modicum of wisdom in this course, but a higher intelligence is evinced by the superintendents of telegraphs in our colonies and dependencies, who render, from time to time, statements of interest, and statistics of value, which enable us to estimate the proportion of errors in a given number of words or messages.

Sir W. O'S. Brooke, in his report of the telegraph service in India, observes:—"In 1859-60 I ascertained that of 105,893 messages sent in Bengal, Bombay, Madras, the East Coast, Ceylon, Scinde, and the North-Western Provinces, 1,605 contained errors, being one message erroneous in every sixty-five. The 105,893 messages contained 2,342,812 words, of which 1,982 are erroneous, being one word erroneous in 1,182." The superintendent of telegraphs in South Australia also furnishes us with some particulars on this subject. He says:—"It may be safely assumed that no important errors or delays, involving pecuniary loss or serious inconvenience, occur which do not come before me. Now, out of the 86,411 messages which passed through our offices during the year 1863, I have a record in my letter-book of sixteen being referred to me containing mistakes; and, as far as my memory serves me, scarcely as many more came under my notice, which were replied to verbally." On home lines the per centage of errors is much less, which may be attributed to the circumstance that the operators are more careful, skilful, and intelligent, than their colonial brethren.

The degree of accuracy attainable is dependent upon a variety of local circumstances, and can only be appreciated by those who have a full knowledge of the practical working of electric telegraphs. On lines where numerous foreign messages are transmitted daily by operators but imperfectly acquainted with languages, there is a possibility of as egregious blunders as would be made by an untaught Esquimaux set to compose a Greek ode. In the telegraphic, as in the printing profession, it is desirable that the manipulator should be able to comprehend a writer's meaning with facility; for as general intelligence is evinced by an operator, in proportion will errors diminish. In the instructions issued by the press to contributors and correspondents, it is insisted that all manuscript be written in a bold, clear hand, on one side of the paper only, or the communication will be consigned to the waste-paper basket. Now, if some such regulation were imposed by the managers of telegraph companies, the public would exercise more care in the preparation of messages, and thus the liability to error in deciphering them would be considerably reduced. In time, improvements may be effected in telegraphy which will render mistakes almost impossible. Inventors, not a few, among whom we may mention Hughes, Lepaul, and Thompson (of Paris), are working to perfect synchronous printing instruments, and if they succeed in establishing them upon our circuits, one fruitful occasion of error will be removed in the "receiving" of telegrams.

The public seem to think that telegraph clerks are infallible, and when a "bull" is made, be the consequence ever so trivial, no condemnation is too severe for the accessory before the fact. "I'll write to the *Times*," is the "boggie" to an unfortunate operator. This is unfair. To publish to the world an instance of default, and to ignore the generally correct manner in which telegraph messages are transmitted, is unworthy conduct, and only receives countenance from the press at the end of a session, when even the lucubrations of a "Bee Master," narratives of pseudo-spiritual *séances*, and disquisitions on nothing-in-particular, prove acceptable. "Mistakes will occur in the best-regulated establishments," and the public (having the right to expect every care to be used in their behoof) should never forget that the telegraph is worked by mutable creatures, who are as often sinned against as sinning in their vocations.

ON THE EFFECTS OF PRESSURE ON INSULATION.

By Amicus.

In the recently published "Report of the British Association for the Advancement of Science for 1863" there appears a contribution from Mr. C. W. Siemens, "On the Electrical Resistance and Electrification of Some Insulating Materials under Pressures up to 300 Atmospheres." This is an important subject rather; and as it appears in the annual of the first association in the kingdom, it is important that its statements, if erroneous, or even doubtful, should not go unchallenged. The "Reports of the British Association" will be cited and quoted from years hence by eminent men yet unborn, as records upon which implicit reliance may be placed; for if they are not the periodical indications of the advancement of science, what are? It becomes our bounden duty, therefore, to sift, examine, and correct everywhere correction is required. And these formidable tomes require the process as much so as less pretentious publications. Greater care, however, should be exercised by those who contribute any "Report of Researches in Science," not only in the making of experiments, but in the way the record *is* made, and the impression that is likely to be consequent thereupon to ordinary readers. We have no right to assume that Mr. Siemens has not correctly recorded the actual results of carefully-made experiments, but we have a perfect right to complain, nay, object, to the conclusion at which he arrives, and the impression which his paper is obviously intended to produce.

The "some insulating materials" experimented on were gutta-percha and india-rubber, and a combination of the two; that is to say, telegraph wires insulated with these materials. It does not appear—but, perhaps, we may assume—that these three descriptions of insulated wire were covered to one uniform thickness; they certainly should have been, in order to obtain accurate results; and the conductors also should have been uniform in construction and diameter: but this was not the case, the gutta-percha line being a strand of three wires, and the india-rubber a single No. 16 copper; while the third was, perhaps, a nondescript altogether, like its insulation. Uniformity in diameter of conductor and insulator are necessary conditions in order to accurate results; consequently, if in no other consideration, these experiments are wholly untrustworthy, since these were wanting; and a careful experimentalist should never think of recording the results of his studies if he is not able to fulfil all the conditions required; still less is he justified in publishing them to the world as irrefragable data for future guidance. Made known as singular phenomena, which might or might not be an approximation to the truth, and which other and more accurate experiments might confirm or explode, no fault could be found with them, and they might justly be classed with many other curious things, which, if they serve no other purpose, have the commendable quality of stimulating inquiry, and conducing to the elucidation of doubtful phenomena.

In addition, however, to this want of uniformity in size and construction of the lengths of insulated wires experimented upon, there is another, and still more grave objection, to be urged against their being accepted as reliable results as to certain conditions under certain circumstances of different insulating substances. One hardly knows what to admire most—the self-satisfied air with which Mr. Siemens quietly assumes the perfectness of the manufacture of his peculiarly constructed india-rubber wires, or the ingenuous candour which admits their infinite inferiority to gutta-percha wires. The eminent experimentalist unwittingly saps the foundation of his own arguments, and proclaims indirectly the utter worthlessness of the experiments he is at so much pains to record.

Except in the imagination of Mr. Siemens, the belief that a good insulated india-rubber line can be made by his process does not exist. The idea of perfect insulation being obtained by longitudinal strips, whose fresh cut surfaces are made to adhere by compression, is happily one that no individual whose opinion is worth anything ever for one moment entertained. They will tell you the process is ingenious, the machine a clever contrivance, and the designer no ordinary man; but they will never assert that he can make a good

wire by the process, still less will they be found to recommend insulated conductors so manufactured. Of course Mr. Siemens sets out from excellent premises. It is an unquestionable fact that fresh cut surfaces of india-rubber will permanently adhere, and become as one solid mass by compressing without the use of any solvent; but no one is so absurd as to believe that the compression at every individual point of an insulated wire, inch by inch, yard by yard, and mile by mile, can possibly be made sufficiently effective as to be implicitly relied upon. The thing is simply impossible without an amount of labour, supervision, examination, and re-examination wholly unprecedented, and in total incontinuity with the production of a core at a reasonable price. Nor is it to be depended on that even then the manufacture would ever be sufficiently satisfactory to warrant its use. Assuming, however, that you succeed in getting perfect adhesion of the rubber strips at every point, it must not be forgotten that you embed between the two strips a hard substance totally incompressible, comparatively speaking; hence, certain portions of the rubber will inevitably be held at a great tension; consequently, when the pressure is removed this portion of the insulation will have a tendency to return to its normal condition, and in doing so will, at a weak point, infallibly sever, in part if not wholly, the point of adhesion, and so the insulation will necessarily become defective. It was a want of confidence in his own invention that first led Mr. Siemens to advocate a mongrel insulation of part gutta-percha and india-rubber, and this combination he at one time asserted to be infinitely superior to either the one or the other singly; but experience having proved beyond all doubt that this combination is the least trustworthy of all species of insulation, on account of the entire absence of consanguinity between the two materials, he abandons both the bantlings which he brought forth with so much labour; and, indeed, had so little love for his own offspring as only to afford them a provisional protection, for he never had sufficient faith in them to complete the patent of either one or the other.

This, then, is the description of india-rubber wire on which Mr. Siemens experimented, and necessarily with most unsatisfactory results—it could not be otherwise. The wire was, without a doubt, defective; if it were not, then it was a miracle of manufacture, since it may with perfect safety be said that a mile of perfectly-insulated wire has never been made by this method, and probably never will. Here, then, is the ground of objection to Mr. Siemens' assumption, that while the "electrification of gutta-percha is increased in proportion to the increase of electrical resistance by pressure, the electrification of india-rubber decreases with the pressure in a ratio surpassing the decrease of electrical resistance." This postulate wants to be differently worded; for "the electrification of india-rubber decreases," &c., read "the electrification of Messrs. Siemens' india-rubber wire decreases," &c., and you will have the correct rendering. Without a doubt the pressure of 300 atmospheres, or half 300, would have the effect of causing Mr. Siemens' novel insulation to split its new spliced sides, and laugh at the futility of such a notion. But although the promising bud of "provisional specification" never blossomed into the flower of "patent completed," still Mr. Siemens did not abandon his production—far from it. A man can scarcely have a higher estimation of his progeny than to believe in their absolute (mechanical here) perfection. Such an overweening regard for one's own may be pardoned, providing it does not lapse into absurdity, and do positive injury to higher interests. In this case a limping, puny, sickly chit is made to usurp the graces, perfections, and consummate proportions of Adonis; and this we might excuse, providing its decrepitude and comatose constitution were not also laid upon his matchless shoulders.

The complaint, then, is that Mr. Siemens should assume that india-rubber is not only improved in the matter of electrical resistance under pressure (in water), but rather deteriorated; and it is objected to because the experiment was made upon a wire, the manufacture of which necessarily entailed imperfectness in the insulating envelope; and every one, therefore, must protest against a piece of egotism which assumes perfection where it does not exist, and publishes to the world as *bonâ fide* results, characteristics of a certain material, from defective and untrustworthy data.

Again, Mr. Siemens is at issue with others who, as authorities, are second to none. We must place our trust in respect to this matter either on Mr. Siemens or the gentlemen who had to do with the experiments conducted for the Government. Professor Wheatstone says (Government Report, p. 286):—"Pressure greatly improves the insulation, but the effect is more obvious as the material is a worse insulator. There appears to be less difference in india-rubber when subjected, and not subjected to pressure, than upon any other of the materials experimented upon." And this is fully borne out by the experiments conducted by Mr. Owen Rowland in the report above quoted from.

That gutta-percha evinces a greater degree of comparative improvement under great pressure is doubtless correct; but that is only a proof of its being a "worse insulator" than india-rubber. It is a more soft and yielding material, and hence "the nearer approach of the particles under the influence of external pressure interferes with their transmission of electrical motion," whatever Mr. Siemens may suppose to the contrary; for if it is to be "referred to the specific atomic arrangement of the material in question," then it is difficult to see how pressure can affect its electrification at all.

Notwithstanding the unjustifiable assumption of Mr. Siemens, and the utterly untrustworthy nature of the experiments he has placed upon record, the paper thus corrected will be productive of good if it results in further and more accurate investigations in this direction. It may be safely asserted that a good india-rubber core has never been submitted to this test; but it is very desirable that satisfactory experiments should be made in order to ascertain the real state of the case.

India-rubber cable manufacturers seem very desirous their material should be adopted, but they are somewhat remiss in making use of the means necessary for the accomplishment of that end. Every imaginable experiment has been made by the advocates of gutta-percha on that substance to show forth its good qualities; and, generally speaking, what experiments have been made on india-rubber have been by the same parties, and, of course, the result has been uniformly to the disadvantage of the latter. If the other party are in earnest, however, it is quite time they combatted their opponents on their own ground. Why not institute their own experiments, and demonstrate to the world that caoutchouc possesses all the essential qualities of a first-class insulator, instead of resting content with making bare assertions merely, and allowing such important matters as these to go undisputed.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

X.

A.D. 1845.—Dr. Remak, in 1845, discovered that certain points favourable for the application of electricity to the human body "corresponded with the points of entrance of the muscular nerves, and that the degree of contraction of a muscle was proportioned exactly to the number of motory nerve-fibres embraced by the current at its point of application." (See Dr. Remak's *Ueber Methodische Electrisirung gelähmter Muskeln*, Berlin, 1845; also, *The British and Foreign Medico-Chirurgical Review*, January, 1859, p. 91, *et seq.*)

A.D. 1846.—Dr. Pring, in 1946, submitted to the Royal Society his process of electro-disruptive etching. The hardest steel is thereby engraved by the disruptive discharges passing between a metal tool and the face of the plate. A galvanic series, in connection with an electro-magnetic coil, is used, the plate being attached to one pole and the tool to the other pole of the arrangement. (See Smee's *Electro-metallurgy*, pp. 337, 338.)

A.D. 1846.—M. Crusell, of St. Petersburg, in 1846, "conceived the idea of cutting and cauterizing the tissues, by means of a wire or a thin plate of platinum, rendered incandescent by a powerful electric current, by making them act after the fashion of a saw, by means of a backward and forward motion." (See De la Rive's *Treatise on Electricity*, Vol. III., p. 687.)

A.D. 1846.—Mr. Hearder, in 1846, constructed his electro-dynamic coil. By means of this apparatus, in connection with a galvanic battery and the condenser of M. Fizeau, sparks can be obtained through an intervening space of air without previous contact. (See Noad's *Manual of Electricity*, pp. 727, 728.)

A.D. 1847.—Professor William Thomson, in 1847, advanced his singularly beautiful theory of electrical images and reflections. (See *Encyclopædia Britannica*, 8th edition, art. Electricity, p. 534.)

A.D. 1847.—Professor Silliman, about the year 1847, successfully copied the iridescent colours of mother-of-pearl by the electro-type process. For this purpose a mould is taken of the shell in fusible

metal, and an electro-cast from that mould. (See Smee's *Electro-metallurgy*, pp. 281, 282; also Timb's *Year Book of Facts*, 1847.)

A.D. 1847.—Werner Siemens, in the summer of 1847, tried successfully a gutta-percha-covered copper wire on an electric telegraph line of from four to five English miles in length, viz., between Berlin and Gross-Beeren. (See *Journal of the Society of Arts*, April 23, 1858, p. 350.)

A.D. 1847.—Mr. E. Loomis, in a letter to Mr. Sabine, dated August 2, 1847, proposes to use Morse's "magnetic telegraph," to determine the difference of longitude between Philadelphia and Washington. (See Abbé Moigno's *Traité de Télégraphie Electrique*, pp. 124-126.)

A.D. 1847, 1848.—Charles V. Walker, F.R.S., in 1847 and 1848, proposed and adopted under-ground wire, insulated with gutta-percha, for electric telegraphs. (See Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 4.)

A.D. 1848.—M. Foucault, in 1848, constructed an electric light apparatus in which the luminous point remains fixed; to effect this, the carbons are moved by clock-work, which is liberated, by the armature of an electro-magnet included in the electric circuit, on the weakening of the electric current. M. Breton's apparatus is similar to M. Foucault's, but instead of springs for approximating the carbons, weights and counterpoises are used; there is also a ratchet wheel and click movement instead of a detent employed to maintain the separation of the electrodes. In Duboscq's apparatus the electrodes have a constant tendency to come into contact, the upper one by its weight, the lower by a spiral spring tending to unwind an endless screw; during the passage of the current the regulating electro-magnets lever armature gears into the endless screw, and prevents the approach of the electrodes by intervening mechanism, but on the weakening of the current the force of the spring preponderates, moves the lower electrode, and revolves a barrel carrying a cord connected with the upper electrode; a pulley of variable diameter, which transmits motion to the barrel, enables the comparative motion of the electrodes to be accurately adjusted, the luminous point thus remains fixed under all circumstances. (See De la Rive's *Treatise on Electricity*, Vol. II., pp. 326-328; also Vol. III., pp. 310-315.)

A.D. 1848.—Dr. Faraday, in 1848, showed that gutta-percha has powerful insulating properties. "When rubbed it shows 'negative' electricity." (See *London and Edinburgh Philosophical Magazine and Journal of Science*, Vol. XXXII., p. 165; also Gmelin's *Handbook of Chemistry*, Vol. I., p. 313.)

A.D. 1848.—Werner Siemens, in 1848, in the bay of Kiel, and in crossing the Rhine at Cologne and other rivers, successfully established subaqueous electric telegraph conductors. (See *Journal of the Society of Arts*, April 23, 1858, p. 351.)

A.D. 1848, 1849.—M. Dubois Reymond, in 1848 and 1849, published his researches in animal electricity. (See *British and Foreign Medico-Chirurgical Review*, January, 1854, p. 126.)

A.D. 1849.—Charles V. Walker, F.R.S., on January 10, 1849, made an experiment of submerging a gutta-percha-covered electric conductor in the open sea. "He attached two miles of insulated wire, submerged in the sea, to the end of one of the wires of the South-Eastern Company's" [telegraphic?] "system at Folkestone, and spoke through it to the Directors in London from the deck of the steamer." (See Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 4.)

A.D. 1894.—Werner Siemens, in 1849, observed the electric charge in underground telegraphic line wires. (See *Journal of the Society of Arts*, April 23, 1858, p. 358.)

A.D. 1849.—Baumgartner, in 1849, made observations which proved the existence of earth currents in telegraphic wires. (See Noad's *Manual of Electricity*, p. 239.)

A.D. 1849.—Mr. W. H. Walenn, in 1849, invented a single-fluid constant galvanic battery, composed of cast-iron, acid sulphate of iron, and prepared zinc. The zinc plate is coated with lead (from a solution of the acetate), and then amalgamated; or it may be immersed in a solution containing lead and mercury. (See *British Association Report* for the meeting in 1849, pp. 45, 46.)

A.D. 1850.—Messrs. Brett, in January, 1850, "projected and obtained concessions" for an electric telegraph line across the Channel. (See Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 4.)

A.D. 1850.—M. Froment's electric telegraph was invented in 1850. This apparatus writes or marks the despatch in conventional signs, by means of a style which cuts as it writes, because it turns round itself in the same time that it makes its to-and-fro movement. The style is moved in a direct manner by the armature of the electro-magnet, and can make from 3,000 to 4,000 vibrations per minute. (See Abbé Moigno's *Traité de Télégraphie Electrique*, p. 104.)

A.D. 1850.—Professor Page, of America, in 1850, described his electro-magnetic engine in a series of lectures which he delivered before the Smithsonian Institution. This arrangement consisted of electro-dynamic helices, which, by their alternate excitement, gave reciprocating motion to iron cores; a connecting rod and crank communicated this motion to a fly-wheel shaft, and thence to the work to be performed. (See Dodd's *Industrial Application of Electricity*, p. 10; also De la Rive's *Treatise on Electricity*, Vol. III., pp. 339, 340.)

A.D. 1851.—Ruhmkorff, in 1851, constructed his electro-dynamic coil. Grove and Gassiot subsequently made researches upon the passage of the electric spark developed by this apparatus in connection with Fizeau's condenser, and made to traverse various media. Poggendorff and Foucault constructed improved instruments of this kind. (See Noad's *Manual of Electricity* pp. 726-730; also De la Rive's *Treatise on Electricity*, Vol. II., pp. 23, 24, and Vol. III., pp. 722-729; also Poggendorff's *Annalen*, t. xciv., p. 289; also *Annales de Chimie et de Physique*, t. xliv., p. 375; also *Comptes Rendus de l'Académie des Sciences*, t. xlii., p. 215; also *Arch. des Sc. Phys. et Nat.*, t. xxxi. of the 4th series, p. 243; also *Comptes Rendus de l'Académie des Sciences*, t. xliii., p. 44.)

A.D. 1851.—Messrs. G. P. and R. F. Bond, of the Cambridge, United States, Observatory, in 1851, read an account of their apparatus for making astronomical observations by means of electro-magnetism to the British Association at Ipswich. This apparatus consists of an electric break-circuit clock, a galvanic battery, and a spring governor, by which uniform motion is given to the paper. The cylinder revolves once per minute, and the observer depresses a break-circuit key at the instant of the transit of a star over the wire or hair line of the telescope, thus making a record accordingly on the paper. This apparatus enables observations to be increased in number, and reduces the personal equation to the minimum. (See *British Association Report* for the meeting in 1851, pp. 21, 22.)

A.D. 1851.—Messrs. Brett, on September 25, 1851, laid an electric telegraph cable of massive construction across the Channel. (See Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 4.)

A.D. 1852.—Mr. Latimer Clark, in April, 1852, noticed the phenomenon of the slow transmission of electric currents through submerged wires. (See *Journal of the Society of Arts*, April 23, 1858, p. 356.)

A.D. 1853.—M. Boulu, from the year 1853, endeavoured to reduce tumours by causing electric excitation to penetrate into the substance itself of the tumours. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 683, 684.)

A.D. 1854.—Dr. Faraday communicated the results of his inquiries, respecting the Leyden jar charge of buried electric conducting wires, to the members of the Royal Institution, on January 20, 1854; he then showed that the electric currents which he employed travelled at the rate of only 750 miles per second along buried wires. (See Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 5.)

A.D. 1854.—Mr. Whitehouse, in 1854, commenced his researches on the possibility of working an Atlantic electric telegraph. (See Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 6.)

A.D. 1854.—Mr. Rutter, in 1854, invented a very delicate electroscope, that rendered the development of human electricity visible to the senses. (See *Encyclopædia Britannica*, 8th edition, art. Electricity, p. 572.)

A.D. 1854.—Dr. Boekel, of Strasburg, in 1854, made regular ozonometric observations in that city, and is thereby led to suppose that a connection exists between the presence of cholera and the diminution of the quantity of ozone in the atmosphere. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 700, 701.)

A.D. 1855.—Dr. Middeldorpff, of Breslau, in 1855, published a work on galvanism as a caustic. He uses three instruments, the "galvanic cautery," the "galvanic porte-ligature," and "galvanic setons." The galvanic cautery consists of a wooden handle, through which wires from the battery pass; the portion of the platinum rendered incandescent is rounded, and it can be turned to useful account when cold. "The galvanic porte-ligature consists of wires that are made to pass either in tubes of glass or of metal and good conducting tubes, but insulated from each other; the cutting handle is made to project beyond the extremity of the tube; the wires that pass through the tubes enables us to give to the terminal handle the volume and extent that are desired." Galvanic setons

consist of platinum wires that are guided through tissues when the object in view is to develope an inflammatory work. (See De la Rive's *Treatise on Electricity*, Vol. III., pp. 687-690.)

A.D. 1855.—Dr. Duchenne, of Boulogne, in 1855, pointed out the different degrees of the susceptibility of the various muscles under the same electric current; also methods of local electrization, by which either the skin or the subcutaneous tissues can be electrized. (See Dr. Duchenne's work *On Localized Electrization and its Application to Physiology, to Pathology, and to Therapeutics*, Paris, 1855; also De la Rive's *Treatise on Electricity*, Vol. III., pp. 611, 633, and 703.)

A.D. 1855.—M. Dubois Reymond, in 1855, gave some lectures on electro-physiology at the Royal Institution, in which the existence of the electric current developed by the action of the human muscles was proved. (See Noad's *Manual of Electricity*, p. 463.)

A.D. 1855.—Mr. Whitehouse, in 1855, showed the effect of oppositely charging a submarine electric telegraphic conductor in neutralizing the Leyden jar charge. (See *British Association Report* for the meeting in 1855; also *Practical Mechanics' Journal*, November, 1855, p. 185.; also Whitehouse's pamphlet, *The Atlantic Telegraph*, p. 7.)

A.D. 1856.—Dr. Andrews, in 1865, proved that ozone is an allotropic modification of oxygen. Ozone has the following remarkable properties:—1. It negatively polarizes metals that have only a weak affinity for oxygen. 2. It is a powerful oxydizing agent. 3. It bleaches vegetable colours. 4. It liberates iodine from a mixture of iodide of potassium and starch paste. (See *Philosophical Transactions*, 1857, pp. 1—13; also De la Rive's *Treatise on Electricity*, Vol. II., pp. 469, 480.)

A.D. 1856.—Professor Matteucci, in 1856, made note-worthy electro-physiological researches, the results of which were as follows:—"Living muscular tissue develops heat by the sole act of its contraction." "The electro-motive power of a cut muscle is independent of the size of its transverse section." "The electro-motive force of the muscle increases with its length." Mammifers have the greatest electro-motive force of muscles; fish and amphibia have the longest duration of this force after death. Any cause that influences muscles also influences their electro-motive force. An instantaneous electrical discharge takes place in a muscle during contraction. (See *Philosophical Transactions*, 1857, pp. 129-143.)

A.D. 1856.—Mr. Whitehouse, in 1856, described an electro-magnetic balance, which gave the "value" of an electric current, telegraphically speaking; he also proved that the "law of the squares" is not the law applicable to the transmission of signals in submarine circuits, but that it is "very little beyond the simple arithmetical ratio." (See *Athenæum*, August 30, 1856, p. 1092; also *British Association Report* for the meeting in 1856.)

A.D. 1857.—Dr. Ziemssen, in 1857, states that the electric conductability of the tissues of the human body is in direct proportion to the quantity of water they contain, also that the central organs of the nervous system, as well as nerve-branches in the large natural cavities of the body, escape the electric current on account of their envelopment in good conductors. With a powerful current, however, these organs may be reached. Dr. Ziemssen also states that electricity is of use in intestinal atony. In his work drawings are given of the position of the points by which to electrically effect the muscles through the agency of the nerves. (See Dr. Ziemssen's *Die Electricitat in der Medizin*, Berlin, 1857; also *The British and Foreign Medico-Chirurgical Review*, January, 1859, p. 91, *et seq.*)

A.D. 1858.—The Atlantic Telegraph Company, on August 5, 1858, received the first signals through 2,050 miles of the great Atlantic electric telegraph cable. This is the day on which the cable was first landed at Valentia. (See *Saturday Review*, August 21, 1858, p. 191.)

THE WORLD-GIRDLE TELEGRAPH.

The playful idea of "Puck" of putting a girdle round the world is rapidly becoming a sober, serious reality. The Governments of Russia and of North America discuss the subject from the most practical points of view—they have measured the distance, tested the climate, counted the cost, and estimated the advantages of such a telegraph, and, what is more, have resolved to give ample encouragement to its construction. We stated some months since that the Russian Government had given a concession to Mr. Collins, an American citizen, for laying a line through the Russian territories in North America up to Behring's Straits; that the British Government had granted facilities for making the line through British Columbia to the Pacific States of America, and that the United States Government had very strongly recommended the carrying out of the plan. In the Old World, Russia is extending its lines of telegraph through Siberia to the Pacific, and England and America stretch forth their hands from the Atlantic to grasp the world-uniting wires. The Hudson's Bay Company are also at work in the same direction, and already the wires and insulators necessary for the construction of a line entirely through British territory to the shores of the Pacific have arrived at the Red River, from whence this line of telegraph will commence its journey. This will give an alternative line entirely through British territory, as far as the boundary of Russian North America, where it will connect itself with the Russo-Anglo-American line.

A short time since Mr. Seward referred the scheme of Mr. Collins to the consideration of the Committee on Commerce in the Senate of the United States. We have been favoured with a copy of his very able State paper on the subject. In it Mr. Seward informs the committee that during all the time that Mr. Collins has been engaged in maturing and developing his scheme, and presenting it to the consideration of Russia and Great Britain, he has been acting under the instruction and with the approbation of the Department of State at Washington. Mr. Seward commences by saying that—

"Mr. Collins is an American citizen, residing in California. He has been, since 1856, commercial agent of this Government for the Amoor River. The public archives, as well as the records of Congress, furnish satisfactory evidence that the country could not have a more enlightened, assiduous, and faithful representative. The project which he submits for the consideration of Congress is the construction of a line of telegraph from some point on the Pacific Telegraph line, or the northern extension thereof, in one of the North-Western States or territories, across the border of the United States and through British Columbia and Russian America to Cape Prince of Wales; thence across Behring's Straits to East Cape, and thence by an inland route across the Sea of Okhotsk to the mouth of the Amoor River. The telegraph line thus proposed is intended, primarily, to connect at the last-named place with a line to be extended from thence to Irkoutsk, the capital of Eastern Siberia. At that important town a line of telegraph begins, which stretches through Tomsk and Omsk, in Western Siberia, Katherinburg on the Asiatic European frontier, Pirm, Kasan, Nijni-Novogorod, and Moscow, to St. Petersburg, the capital of the Russian empire. The line projected by Mr. Collins, from the Pacific Telegraph to Amoor River, with its anticipated extension by the Russian Government to Irkoutsk, would be the one link now wanted to supply direct and unbroken telegraph communication from Cape Race, in Newfoundland, on the eastern coast of America, across the eastern and western continents and the Pacific Ocean to Cape Clear, in Ireland, the westernmost projection of Europe. When a submarine cable shall be successfully laid between Cape Clear and Cape Race, it will, together with the link I have last before described, complete a telegraphic circuit around the earth between the parallels of forty-two degrees and sixty-five degrees of north latitude. Three questions arise from Mr. Collins's memorial, namely:—First—Is the enterprise feasible? Secondly—Would it be useful? Thirdly—Has it a just claim on the Government to the patronage which he solicits? The most prominent physical difficulty is the extent of territory to be traversed. The starting point must be chosen in either Nebraska, Kansas, Colorado, Utah, Montano, Idaho, Oregon, or Washington. Thence the distance to the line of British Columbia would be about 1,000 miles; the distance to be traversed through British America to the line of Russian America, about 600 miles; the distance through Russian America to Cape Prince of Wales, about 1,900 miles; the length of a submarine cable across Behring's Strait would be forty miles; and the distance from East Cape, by an inland passage around the Sea of Okhotsk, and through the settlements of Okhotsk, Ayan, and Shantar's Bay, which are well-known stations of the whale fishery, to the mouth of the Amoor River, would be about 2,500 miles. The entire length of the line would be about 6,040 miles. Operative telegraph wires have already been stretched on this continent of the aggregate length of 70,000 miles; and similar wires have been stretched, on the eastern continent, of the aggregate length of 200,000 miles. Operative submarine telegraph wires have been laid of the lengths, respectively, of 300 miles and 500 miles, from Dover to Heligoland, and from Malta to Tripoli. Thus it is seen that the mere extent of the route to be traversed in the present case, does not constitute an insurmountable, nor even a serious difficulty. The physical obstacle which next presents itself is the surface formation of the regions to be traversed. That portion of the route which lies within our own territory is chiefly mountainous; and the projected telegraph line must at least course along declivities of the mountains, even if it should not be found necessary, in one case, to surmount them. British Columbia presents a similar topography. But there the mountains are divided into three ranges, whose courses are from north to south, while intervening valleys invite the introduction of telegraphs and roads. The Pacific coast of Russian America is chiefly level. The portion of Siberia which lies between East Cape and the head of the Sea of Okhotsk is, for a large extent, a steppe, or plain, with gentle elevations occasionally rising into mountainous ridges. At the head of the Sea of Okhotsk a range of mountains must be crossed, and the region lying

between that range and the mouth of the Amoor River is of the same character as that before mentioned, which extends from the same range northward to East Cape. The highest elevation to be overcome on the whole line would be found on the Rocky Mountains, within the United States; and this elevation may be estimated at 8,000 to 10,000 feet. Operative telegraph lines have already been stretched over steppes, in both continents, similar to those thus described. The Pacific Telegraph line, in crossing the Sierra Nevada, rises to an elevation greater than that which is to be surmounted on the line now under examination. With the exception of timber, all the materials of a telegraph line are light and portable. Metallic wire sufficient for a mile of telegraph, together with the materials for insulation, weighs not more than 400 lbs. Sufficient timber awaits the builder along the route through the United States and British Columbia. Timber is also found on those portions of the projected line which lie within the Russian dominions, on each continent, with the exception of a timberless steppe, 500 miles wide, on each side of Behring's Strait. There the needful timber can be brought near to the line, either by sea or from the forest-covered shores of navigable rivers. The temperature of the region through which the northern part of the lines would pass is very low. Nevertheless, winter is less severe than it is between the same parallels of latitude on the Atlantic coast. The telegraphic line which connects St. Petersburg with Archangel on the White Sea, and also the telegraphic line which passes around the Gulf of Bothnia and connects St. Petersburg with Tornea, are maintained in operation without difficulty, although they cross as high parallels of latitude as those which lie in the way of Mr. Collins's line. The waters of Behring's Strait are about 180 feet deep, and they are frozen through one-half of the year; but the congealed mass, when broken, generally takes the form of anchor ice, and not that of icebergs. Thus, climate seems to offer no serious obstacle to the enterprise; while it is not entirely unworthy of consideration that in cold latitudes timber used in any necessary structure is less perishable than timber used in warm latitudes, while less of insulating material is demanded in high latitudes than is required in more genial climates.

"The only political difficulty in the way of the enterprise is the fact that it requires concerted aid from three several States, viz.—The United States, Great Britain, and Russia. The two last-named Powers have already, with enlightened and fraternal liberality towards the United States, made all the concessions which were demanded. Therefore, if Congress shall grant the application of Mr. Collins, no political obstacle will remain.

"The result of the survey of facts thus far made is, that there are no insuperable obstacles, either physical, political, or social, in the way of the projected line of telegraph.

"In regard to the expense which it requires, Mr. Collins estimates the whole cost at five millions of dollars. A just legislative caution would probably induce Congress to double that estimate. I understand that an association is already formed, with a capital of ten millions to be devoted to the enterprise. I am, therefore, of opinion that is is entirely feasible.

"As to the probable usefulness of the enterprise. It is quite too late at this day to debate the abstract question of the usefulness of the magnetic telegraph. It would be as easy now to dispense with the steam-engine on land or on sea, in the business of commerce, in social intercourse, or in political affairs, as it would be to forego the use of the telegraph. To be without it, is to be isolated. Other conditions being equal, the country that has the largest extension and the most thorough radiation of the telegraph wire enjoys the most active and profitable system of domestic commerce. Of the 70,000 miles of telegraph now in operation on the American continent, 60,000 miles are found within the United States, and the remainder in the provinces of British America. But commerce on the American continent defies political restraint and centralizes itself within our own country. For practical purposes, we may regard the whole telegraph system of the American continent as our own. But internal commerce imparts life to, and receives new life in return from foreign commerce. In proportion to the extent and variety of its resources, the nation that enjoys the most prosperous foreign commerce exhibits the greatest industrial activity and domestic happiness within its own borders. The vigour which commerce has already attained among us, while we continue to hold our communications with the eastern continent by navigation only, is justly a subject of national congratulation. Can there be a doubt that if our telegraph system should be connected by a trans-oceanic line with the one that is now performing its equally isolated part on the eastern continent, new and stronger reciprocity would be exhibited, not only in commercial centres, but in every recess of the land?

"Every one, knows, however, that neither the American nor the European system has yet attained to its ultimate development. Transient wars now delay the establishment of wires in Pensacola, Havana, San Juan, Panama, Quito, Lima, Valparaiso, Buenos Ayres, Monte Video, Rio Janeiro, Surinam, Caraccas, and Mexico, and the incorporating of them, with all their local ramifications, into one American telegraph system. On the eastern continent neither the domestic disturbances nor the rivalries of States, nor their occasional collisions, prevent a continual expansion of the telegraphic system. The telegraph construction of Russia at this day, like her system of railroads, presents the frame-work of an imposing structure, the dimensions of which are boldly outlined, while the connections and extensions yet remain imperfect and unfinished.

"When we take into consideration the fact that Russia has already brought all her chief inland markets and mines, as well as her principal ports on the coasts of the Arctic Ocean, into telegraphic communication with her capital, it is readily perceived that, by offering to co-operate with us in giving effect to Mr. Collins's design, Russia actually invites us to put forth our national energy from every point within our borders where industry of any kind dwells, and especially from our North Western and Western States, and apply that energy in the great work of renewing and restoring the long-languishing civilization of the regions where our race first impressed its dominion upon the globe appointed for its residence.

"It is important to remember that the telegraph wire is as yet a newly-invented instrument, timidly employed and clumsily handled, with a very imperfect knowledge of the fulness of the power that resides in it. It costs us now one-half a mill per mile to speak a single word through the cheapest telegraph wire of any considerable length. This is vastly more costly than the average transmission of messages in writing by employing the steam-engine, either on land or on water. This great expense of telegraphic communication is due, however, not at all to any inseparable quality of the telegraphic machine, for that machine is easily constructed of very simple and cheap materials. The expensiveness is due to two transient conditions of the telegraph system:—First, the charges now justly imposed upon it for rewarding the inventors; and, secondly, the fact that, as yet, fixed habits of communication in ancient forms prevent frequent resort to the new mode of correspondence, and customary investments of capital which are sufficiently remunerative cause it to be sparingly applied to the perfection of the new system. When these merely ephemeral embarrassments of the magnetic telegraph shall be removed, the magnetized wire will become, for the chief purposes of social, commercial, and political communication, as practical as, by reason of its adaptation, it is effective."

Mr. Seward concludes by saying:—"It seems to me that in extending dominion over inland mountain regions, and setting up the National flag on the Pacific coast, the American people, however inconsiderately, assumed the duty of diffusing an equal civilization throughout the whole of the great country which they thus included within their borders. Nor would it be wise to shut out from our thoughts the consideration which necessarily results from contemplating calmly the positions and the resources of our new North-Western and Western States. It becomes our duty to act upon the conviction that, from this time henceforth, those States are to perform an important part in a great work which shall make the shores of the Pacific Ocean the home of communities that shall be as busy, as prosperous, as free, as enlightened, as powerful, and as happy as those which now cluster upon the Atlantic shores. The Atlantic States, by their intermarriage with those of the Pacific, have come under an obligation to favour this great development. What Mr. Collins asks of Congress is, the grant of a right of way across the public lands, with the right to take therefrom materials necessary for constructing the line; the use of a national vessel, suitably officered and equipped, to make surveys and soundings along the North Pacific coast, beyond the limits of the United States, and to aid in prosecuting the work; and, finally, a stipulated compensation for the Government use of the line, when it shall be constructed. If the views I have submitted are just, this demand for patronage is neither unnecessary nor unreasonable. We could not withhold it without showing a want of appreciation of the liberality and friendship which have been manifested towards the United States, by Russia and Great Britain, in the proceedings they have adopted towards the same enterprise. I do not know any one object lying within the scope of our foreign relations more directly important than the preservation of peace and friendship with those two great and enlightened Powers. Nor can I conceive of any one measure of national policy that would more effectively tend to secure that great object than the construction of this proposed intercontinental telegraph. I forbear to urge the project in competition with the proposed line across the Atlantic from Cape Clear to Cape Race, which, notwithstanding past difficulties, I yet hope to see speedily completed. The two lines would naturally aid and strengthen each other. If they should even come into competition, it would be more advantageous to the world to have the use of both than the use of only one of them. One might be expected to operate when the other should be accidentally suspended. Nor can it be reasonably doubted that the great interests of human society will, at a very early period, require more than one, and more than even two, trans-oceanic, world-encircling telegraphs."

[The substance of the State record, from which our contemporary, the *Railway News*, quotes above, has previously appeared in these columns.—Ed. T. J.]

ANNUAL REPORT BY CHAS. TODD, Esq., SUPERINTENDENT OF TELEGRAPHS, &c., SOUTH AUSTRALIA, 1863.

(*Concluded from page* 166.)

Extract from the appendix relative to the proposed telegraphic communication between the Australian colonies and Java. Mr. Todd says:—

To refer, in the first instance, to Mr. Gisborne's scheme. It appears from his letters to Sir George F. Bowen that he and his co-promoters are prepared so far to meet the views of the colonies as to agree to terminate their cable at Van Diemen's Inlet, on the east side of Carpentaria, thus reducing the length of cable (from Cape Sedano, East Java) to 1,855 nautical miles, requiring a capital of £710,000 (increased in a subsequent letter to £725,000), for which a subsidy of £35,500 is asked on the same terms as before.

It will be remembered that the original scheme, which provided for the

cable being laid to Brisbane, was estimated at £1,100,000, with a subsidy of £50,000.

To the £725,000 we should, of course, have to add the cost of the land section from Van Diemen's Inlet to Brisbane.

In consenting to alter their plans, Mr. Gisborne goes on to say, "But as the English public are not in a position to judge of the feasibility of constructing within a specified time, or of afterwards efficiently maintaining, the proposed overland telegraph, the promoters will require the following conditions:—

"I. That the Government of Queensland shall construct and maintain an overland telegraph between Brisbane and Van Diemen's Inlet within one year and a half from the date of the contract, granting the subsidy for the cable between Java and the said Inlet.

"II. That for every day beyond the said one year and a half which shall elapse without telegraphic communication being completed, and after its completion for every day that such telegraphic communication shall be interrupted between Brisbane and Van Diemen's Inlet, the Government of Queensland engage to pay to the company at the rate of ten (10) per cent. per annum upon the cost of the said submarine line."

The foregoing conditions, it is observed, are only a counterpart of the similar condition which provides for the infliction of a penalty on the company whenever the submarine line may be interrupted. The 10 per cent. thus deducted from Queensland would go to pay the working expenses of the company.

On the two foregoing conditions I have only to remark that the time allowed for the land-line being erected, though perhaps ample, might, without disadvantage, be extended to two years; at all events, the payment of 10 per cent., required in the second condition, should not commence before the expiration of two years from the date of signing the contract: presuming, of course, the cable to be laid, and in efficient working order at that time.

The promoters, represented by Mr. Gisborne, are prepared to lay cables, of the kind specified in Messrs. Forde & Fleeming Jenkin's letter, from

	£	s.	d.
Rangoon to Singapore, at estimated cost of . . .	450,000	0	0
Singapore to Batavia " " . . .	170,000	0	0
Java to Gulf of Carpentaria " " . . .	725,000	0	0
Total estimated cost	£1,345,000	0	0

With regard to the first section, we learn that the Secretary of State for India cannot entertain the proposition until the Treasury is prepared to assist in its further extension to Australia, from which it may be inferred that this portion of the line of communication would be carried out simultaneously with the line to Australia; and the second section, from Singapore to Java, is dependent on the carrying out of the first, the Dutch Government having agreed to pay a subsidy of £8,500 for thirty years, subject to the completion of the line from Rangoon.

The third, or Australian section, it is proposed should be laid in the following manner:—

Cape Sedano to Coepang		590 knots
Coepang to Port Essington		525 "
Port Essington to Cumberland Straits		285 "
Cumberland Straits to Van Diemen's Inlet . . .		430 "
Total, direct		1,830 "
Slack cable, 5 per cent.	92 knots	275 "
Repairs, 10 per cent.	183 "	
Total cable provided		2,105 "
Of which, Main cable	1,855 knots	
Shore ends	250 "	
		2,105 "

The promoters now ask the Imperial Government to assist the undertaking by the payment of one-fifth of the subsidy; that promised, they would be prepared, they state, to at once register themselves as a company.

It was not, however, to be expected that the home authorities would give any promise of pecuniary aid to a scheme of this kind without reference to the colonies most interested, and who, in the event of its being finally carried out, would have to pay the greater part (four-fifths) of the cost; the matter has accordingly been remitted to the several Australian Governments with a view to joint action being taken, without which nothing can be done. There can be no doubt that the Imperial Government will be quite willing to contribute its fair quota when we have decided amongst ourselves as to the best plan to be pursued.

Should the Home Government consent to subsidize Mr. Gisborne's line, or, which would be the same thing, to provide one-fifth (1/5) of the capital, the subsidy might be apportioned somewhat as follows:—

Home Government	£7,100	0	0
Victoria	12,425	0	0
New South Wales	7,100	0	0
South Australia	3,550	0	0
Queensland	1,775	0	0
New Zealand and Tasmania	3,550	0	0
	£35,500	0	0

Allusion is made to the course pursued in South Australia with reference to the question under consideration; and it has been represented that this colony has advocated a line from Spencer's Gulf to the North Coast, from a selfish desire to promote her own immediate interests, without regard to its practicability or expediency. Such is not the case. The line across the interior has only received support because it would be the most direct, and therefore, since recent explorations have proved that no very great physical difficulties exist, the less costly.

As a great deal of misconception prevails on this point, which, by evoking a spirit of jealousy, cannot fail to operate more or less injuriously in the consideration of this important work, I feel it necessary to state most distinctly that this colony would derive no exclusive advantage; nor practically any priority of intelligence of commercial value, from its geographical position, should the line here proposed be adopted. Suppose, for instance, the communication to be viâ Adelaide, and thence by existing lines to the neighbouring colonies; practically, a message addressed from London to Melbourne would be delivered as soon as one simultaneously addressed to Adelaide. A merchant in Adelaide, simply because the line passed first through South Australia, would have no intelligence that would not be equally and as early accessible to a merchant in Melbourne. In a commercial point of view, therefore, we should obtain no advantage over other colonies by Stuart's route being followed.

The misconception I have referred to arises from persons, ignorant of the actual working of the telegraph, supposing that we should in some way be the first to receive valuable information, of which, if we pleased, we could take advantage before it could reach Melbourne and Sydney. In fact, I have heard persons say, in dilating on its importance to us, that we could sell the news. A similar notion was recently held with regard to "mail news," whereas Melbourne being the larger place, it would not unfrequently happen, as it does now when the mail comes in, that "foreign telegraphic intelligence" would be received from Melbourne which had previously traversed the whole length of South Australia. I have adverted to this because of its obvious mischievous tendencies.

The real question to be considered is that of cost. The colonies are mutually interested in securing the most serviceable and least costly route—that which offers the greatest advantage at the least expense, whether it be that now proposed by Mr. Gisborne or any other. It is not a question which colony will be most benefited, but which line will be the best and cheapest.

On the one hand the promoters, as such, would naturally prefer as great a length of cable as they can get us to agree to, upon which they would derive the more profit in its manufacture, and the larger subsidy in its after working. On the other hand, the colonies are interested in reducing the cost to a minimum, consistent with the success of the enterprise, and will consequently desire to push forward their land-lines, which will besides facilitate the opening up, and settlement of, the country—a consideration which cannot be viewed with indifference. Mr. Gisborne is incorrect in saying that, in advocating a land-line, neither South Australia nor Queensland contemplate sparing any outlay on the part of the other contributing colonies; since it is quite clear that, by shortening the sea line and thus reducing the cost and consequently the annual subsidy, the amounts contributed by each colony will be proportionately diminished.

I now come to Mr. Walters's correspondence, which, although extremely valuable, need not detain me long, inasmuch as the important suggestions he offers, and the information he has gathered, are in the main coincident with the views I have all along expressed. Mr. Walters is evidently unaware of this, and his recommendations are invested, therefore, with the greater force, being based on altogether independent sources of information, and yet confirming and supporting the course I have throughout advocated.

The purport of the correspondence furnished by Mr. Walters may be summarized as follows:—1. The plans of Mr. Gisborne and his co-promoters are unnecessarily costly, cheaper routes being available. 2. The saving to be effected by, and for other reasons the advisability of, the Governments dealing directly with the manufacturers of the cable, instead of with the promoters. 3. The desirability of appointing one consulting engineer and electrician, who should alone be held responsible, instead of a board with divided responsibility. 4. To submit Mr. Passmore's offer to construct and lay a cable from East Java viâ Timor to the north coast of Australia, and to erect from thence 1,100 miles of land-line. 5. Sundry valuable hints as to the mode of procedure in the construction of the line and after working it.

With regard to the first, Mr. Walters has rendered important service in bringing so prominently before his Grace the Duke of Newcastle the great saving to be effected by the erection of a land-line over a great portion of the distance, a course which our better knowledge of the interior had shown to be perfectly practicable.

The cost of the modified scheme put forth by the promoters is, as we have seen, £725,000, to which must be added the cost of the land-line to Rockhampton, estimated by the late Mr. J. J. Austen at £120,000; or, putting the latter at £100,000, the cost of the whole would be £825,000.

The cost of the line from Port Augusta to Cambridge Gulf, and thence viâ Timor to East Java, I have before estimated at £403,200. If the cable is landed at the Adelaide River we shall increase the distance; but we may safely set it down at £450,000.

A line from Rockhampton to the Adelaide River, and by cable to East Java, would be about the same. In either case we have a saving of something like £375,000.

As mentioned in my last annual report, Mr. Cracknell, the superintendent of telegraphs in New South Wales, has recommended the last route; the first portion from Peak Downs to, say, 138° east longitude, to be erected at the joint cost of New South Wales and Queensland; to be continued thence by South Australia through her newly-acquired northern territory, to some suitable point on the coast, which would give 1,000 miles (reckoning from Port Curtis) to be constructed by the two former colonies, and 600 by South Australia. Should we decline to carry it on, Mr. Cracknell proposes to terminate the line at the Albert River, which would practically fit in with Mr. Gisborne's project.

It will, perhaps, induce greater confidence in my figures to find them so closely in accordance with the independent estimate made by Mr. W. B. Passmore, of London, a gentleman of considerable experience, who, in a letter addressed to the Agent-General (14th March, 1863), estimates the cost as follows:—

Submarine cable from East Java to Timor, and thence to nearest landing-place on the north coast of Australia . . . 940 knots.

	£	s.	d.
940 knots at £250	237,000	0	0
Land section, say 1,100 miles from coast to some central point	175,000	0	0
	£412,000	0	0

In a letter to the Right Hon. the Chancellor of the Exchequer (24th March, 1863) he undertakes to construct and lay a cable from East Java to the north coast of Australia, and from thence a land-line to any point in the interior, not exceeding 1,100 miles, for the sum of £412,000. This offer Mr. Passmore is still prepared to stand by, and is waiting the decision of the Colonial Governments.

I may, moreover, add that my estimate for both the submarine and land sections has been supported by Mr. Cracknell and the late Mr. J. J. Austen. It is satisfactory also to find that the views I have so frequently expressed as to the feasibility and superiority of a land-line are so strongly supported by Mr. Cromwell Varley. In his letter to the Agent-General of the 17th March, 1863, he observes:—"1st. The first cost of a land-line is very much less. 2nd. The maintenance is much more facile and inexpensive. 3rd. The lines being comparatively free from the effects of induction, are manipulated with greater ease and expedition, and fewer errors creep into the despatches during transmission in consequence. 4th. The various sections of land-line can be united together by translating instruments, so as to afford direct communication over distances of even 2,000 and 3,000 miles at a good commercial speed. We often work from London to St. Petersburg direct at a rate of eight to twelve words a minute. 5th. Submarine circuits, owing to the retarding action of induction, cannot be so united without too great a loss of speed, unless the core of the cable be extravagantly large."

In reply to the objections raised against the lines being carried across a comparatively wild country, he points to the recently-constructed line between New York and San Francisco, a distance embracing more than three hours of longitude, "which line of telegraph is entirely overground, and crosses the snow-covered Sierra Nevada and Rocky Mountains, passing through deserts and over 1,500 miles of country inhabited by savage tribes; the stations are from 30 to 75 miles apart." This line has been in operation for the last two years with scarcely any interruption.

There is no reason why the Governments should not contract for the cable direct with the manufacturer, and thus save the profit that would otherwise go into the pockets of the promoters. In any case, I am strongly of opinion that the manufacturer should be made responsible for laying the cable, and for its efficiency during the first year of its working. That would make his interest identical with that of the Government in producing the very best article possible with our existing knowledge.

The design of the cable should be as much as possible left to the manufacturer; but previously submitted for the approval of the consulting electricians.

After the form of cable has been decided on, the duty of supervision and testing during its manufacture had better be left to one electrician appointed by the Government; and there is no one whom I could recommend more confidently than the gentleman named by the Agent-General—viz., Mr. Cromwell Varley. By adopting the course I have suggested we should avoid what has been one of the most fruitful sources of failure in these undertakings—divided responsibility. The chief safeguard, however, would be to make the manufacturer responsible for the cable for one year after being laid.

In Mr. Fortescue's letter to the Agent-General of the 9th July, his Grace the Duke of Newcastle suggests, at the instance of the Lords Commissioners of the Treasury, that the several colonies should appoint representatives to meet for the purpose of discussing the question in all its bearings.

The Agent-General, in several instances, urges the same course, and it must be manifest, as I have repeatedly stated, that no progress can be made without co-operation among the colonies; and, as the best means of securing that, I would respectfully suggest that a communication should be addressed to the other Governments, advising a meeting at Melbourne of the superintendents of telegraphs in Victoria, New South Wales, Queensland, and South Australia, during the present summer. And I would submit the following suggestions for the consideration of the Government:—1st. That it is important to have as little cable and as much land-line as is practicable. 2nd. That the Government should deal directly with the manufacturer in procuring the cable. 3rd. That it would be unwise to invite tenders for the cable, but that the market price should be charged for the materials with an allowance to be determined for profit, offers being obtained from two or more manufacturers. 4th. That a board should be appointed in London, at which each colony and the Home Government should be represented, assisted by competent advisers in selecting the best form of cable, &c. 5th. That at least one paid consulting electrician and engineer should be appointed to watch the cable during every stage of its progress. 6th. That the manufacturer should design and furnish samples of the cable to be supplied. 7th. That the manufacturer should be held responsible for the proper shipment and laying of the cable, and further be responsible for its integrity and efficient working order for one year after the whole shall have been laid. 8th. That the land-line be erected by contract, under the superintendence of the Governments through whose province it may pass. 9th. That on the completion of the line the whole, or at least the submarine section, should, if possible, be leased. If the maker of the cable will farm it, as has been done in the case of the Malta and Alexandria cable by Messrs. Glass, Elliot, & Co., so much the better. If the line is leased proper provision must be made for renewal, a fund being set apart annually for that purpose. 10th. That the line should be constructed at the joint cost of the Home Government and the several colonies: the former contributing, say, one-fifth (⅕th), and the latter four-fifths (⅘ths), to be equitably apportioned on the basis of population, or the existing ocean postal subsidy. Or should the line, or any portion of it, be subsidized, then a similar division of such subsidy.

I would add, in conclusion, that although it is desirable, for obvious reasons, for an early conference to be held, no further steps towards the actual construction of the line ought to be taken until we have had at least six months' experience of the working of the Persian Gulf cable.

Mr. Passmore's offer would, of course, be considered in conjunction with Mr. Gisborne's at the proposed conference.—I have the honour, &c.,

CHARLES TODD,
Observer and Superintendent of Telegraphs, South Australia.

The Hon. the Commissioner of Public Works.

CORRESPONDENCE.

MR. BRITTAN'S PLAN OF COMMUNICATION BETWEEN GUARDS AND DRIVERS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—A whistle on the roof of the guard's van, worked by air compressed by the wheels of the carriage, was tried some ten years since on the Lancashire and Yorkshire Railway, if I am not mistaken. Would it not be undesirable to *weaken the significance* of the engine whistle by using it for any other purpose than that for which it is now employed?—Yours,

Bristol, 4th October, 1864. R. S. CULLEY.

MR. PREECE'S ELECTRIC SEMAPHORE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Will you kindly give a description of Preece's electric semaphore, referred to in your remarks on Colonel Yolland's report on the Sowerby-bridge accident in your last number, or say where any can be seen in actual working, as all the electric signals I have yet seen (if in connection with a semaphore or disc) have been useless, and could not be depended upon for one day. Even the use of such a signal would not, as stated in the last paragraph of your article, "dispense with the use of the hut, the man, the semaphore, and the distant signal," as the man being there to protect the tunnel by means of double-needle instruments on the "block" system, it is only policy to give him a semaphore and distant signal to work.—Yours obediently, ARCHIMEDES.

Manchester, 3rd October, 1864.

THE ORAN AND CARTHAGENA TELEGRAPH CABLE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—You would oblige me, and very likely satisfy a great number of your readers, by giving news of the Oran and Carthagena cable. The news received in Paris from Algeria prove by their date that they come by post, and not by telegraph; so there is no doubt that the cable has been broken; but no official information of the accident has been already given. Very likely the English newspapers will first give notice of the failure, because the French Government having some interest engaged in the question, the French will only speak of it after the *Moniteur.*—Yours sincerely, UN ABONNÉ.

Paris, 1st October, 1864.

[We should have been exceedingly glad if we were able to furnish our esteemed correspondent with the information he requires about the Oran and Carthagena cable; but unfortunately we also on this side of the Channel are kept in oblivion with respect to the vicissitudes of submarine telegraphic lines. Government officials and contractors have combined together to set at naught the right of the public to be informed of the state of its property. We shall, however, endeavour to ascertain the present state of the cable in question.—ED. *T. J.*]

TELEGRAPHY AT THE BRITISH ASSOCIATION.—MR. J. B. THOMPSON'S INDUCTION MACHINE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—There is a criticism put forth this week in your journal on the "electrical science and its attendant submarine telegraphic science"—by the way, I should say telegraphy was Art, as represented at the meeting of the British Association at Bath. Now, on all occasions discussion is good if it be entered into with fair and honest intentions; for though the critic may not be equal to the task he has assumed, or he may misunderstand the matter in hand or the statements criticised, yet he will be willing to be put right on these matters, if he have no other object than just the truth of the matter.

In the present case "Amicus," apparently honestly, sets things down just as they appear to him, though somewhat hastily, before having thoroughly understood the subject or the statement of it. Of course I speak only of that portion of the critique which is devoted to my sayings and doings.

Before beginning with me "Amicus" prays to the Fates to keep him from getting out of his depth. Well, I do not think that he need to do that, if he had considered the thing a little before rushing into it. As it is, he flounders about and muddles the matter, and then pretends that he is afraid of getting out of his depth because he cannot see the bottom. It is possible that this may be a pretence, and that he huddled all these absurdities together so that he might appear funny; but "Amicus" should not forget that scientific matters are not discussed in that way. Scientific men are in the habit of first stating fairly that which they would criticise; then, with sound reason, they support their view of the matter; and after fair discussion, if the opposite be found to be absurd, then "let him laugh who wins." After all, it may be all done in good faith, and this is the very best that he can make of it. In that case, I am only too happy to be able to assist him.

First, he seems not to know exactly what theoretic views I would wish to put forth for discussion; he seems to take it that I am trying for the first time to show that electricity is not matter but energy: that is too great an honour for me to claim. I will refer him to Drs. Joule, Scoresby, and Faraday for that. He says that my "theory remorselessly overturns the prevailing ideas of light and heat, and necessarily of electricity and magnetism also." Now this is an error on our *friend's* part—one of ignorance, I presume, from what he says of light and heat. He says that I consider the "indulating" theory of light as old-fashioned. I did not know that there ever was a theory that did indulate, and if there had been such a theory, the sooner it was old-fashioned the better—such a shaky affair, you know. If "our learned friend" means the undulatory theory, then what is he dreaming about? If he knows anything about the matter in discussion, he ought to know that this theory is the solid ground from which I take my departure in my reasonings on the excitation of electricity and magnetism; whether I reason rightly or wrongly is another matter, and remains for discussion.

I take it for true that it is established that sound is by the indulations of the air, light of the æther, and heat of the ultimate particles of all matter; this last has been clearly set forth by Professor Tyndal. If our friend finds fault with me for considering heat, light, electricity, and magnetism as different forms of force, I cannot help it. I must continue to do so till he shows me a reason for altering. In the meantime, he can go on charging his wire with the two electric fluids, if he so please, without any interference of mine.

And now I will state what my theoretic notions on electric induction are, and wherein I conceive they differ from the notions hitherto held on that subject. First, it is believed that, in producing electric induction by means of an electro-magnet, it is the voltaic electricity used which produces the induction immediately, and not mediately; for it is said that all you can do by induction is to turn quantity into intensity. If it were as supposed, then the conclusion would be correct, according to the law of conservation of forces, and at first sight it looks as if it were so; but there are facts in induction which appear not explainable by it. The phenomenon of electricity undoubtedly exhibits a species of motion, whether you consider it a motion in the ultimate particles of the conductor or that there is some fluid flowing through it; whichever way it is, then, it is the motion that is induced. It follows, then, if the electricity of the battery by its fluxion produces the flow of induced electricity, that while the battery electricity continues to flow the induced electricity must also continue to flow, for while a cause continues to act the effect must continue to appear.

But it is well known not to be so; it is only on the instant of completing the battery circuit that the induced electricity appears, and it does not continue while the battery current flows, but again appears when the battery current ceases. It is clear, then, that the battery current as such does not produce the induced current, because for one battery impulse we have two induction impulses, and that in opposite directions, and not one continuous current while the battery current flows. We must look further, then, for the cause of induction; and the only other noticeable phenomenon connected with it is magnetism. It is proved that wherever there is an electric current there is magnetic excitation, whose polarity is at right angles to the current of electricity. A spiral current of electricity produces a sphere of magnetism; but this expression seems to offend our friend. I dare say he has strewed iron filings on a piece of cardboard and held it over a magnet, and has observed the filings arrange themselves into a series of regular curves. That which causes the filings to assume that form I call a magnetic sphere. Now this sphere has no motion but on its projection and recession. This also can be proved to any one. Take an electro-magnet, and place it with one or both poles upward, and over these poles place a card with iron filings upon it. Then, on making battery contact, the filings will rise up at right angles to the current, and on breaking contact they will fall down into their former position, and this as often as contact is made and broken; but between making and breaking contact there is no motion in the magnetic sphere; yet all this time there is a continuous motion in the electric current. This also can be shown by placing a voltameter in the circuit. I think these simple experiments clearly prove that it is not the flow of the voltaic electricity which produces the induction. The flow of the induced electricity does not coincide with the flow of the voltaic electricity, neither as to direction nor time; but it does agree with the projection and recession of the magnetic sphere, both as to direction and time; therefore, it appears to me that it is a warrantable conclusion to draw, that it is the motion of this magnetic sphere which produces the electric induction. This can be further confirmed by mechanically projecting a magnetic sphere across a spiral coil of insulated wire. Pass a magnet within such a spiral coil, and of course you will project the magnetic sphere across the spirals with the magnet, and also you will produce a current of induced electricity, and on withdrawing the magnet another, but in an opposite direction.

These are two or three facts out of very many which any one who understands the matter might adduce in support of this theory of electric induction. Very likely our present friend, or some other, will say, what odds whether the induction is produced by the voltaic electricity or by the magnetism which it excites? Great odds, my friends. It is then no longer a grinding of quantity into intensity. The voltaic electricity then simply prepares a way for the influx of the earth magnetism. And if it be an axiom in mechanics that action and reaction are equal, then it is practically of the utmost importance; for each of the induced currents of electricity should be equal to the one current of voltaic electricity. The magnetic force should be equal to the cause which excites it, and the induced electricity should be equal to the motion of the magnetic sphere which produced it; therefore, it should be equal to the voltaic electricity which excited the magnetism.

Now, according to the axiom the reaction of the magnetism will produce another induced current equal to that produced on its projection, and for this there is no expenditure of electricity; therefore, by electro-magnetic induction the electro-motive force is multiplied. So much for the theory; experiment only can confirm or disprove it. As to its practical application in the machine I need not say much, for everything that our friend says on that proves that he has not seen it, consequently cannot understand it, and certainly does not. It is not like a Rhumkorf at all, any further than this, that it has spirals of copper wire in it; yet these are not the same as in a Rhumkorf, and in every other respect it is perfectly different. It is not strained to produce its effect at all. It is governed by precisely the same laws as batteries for moderate tensions, and for high tensions it gives much more quantity than a battery of equal tension would do, and can be applied to every purpose for which a battery is used.

I should be glad that any one who wishes to criticise it should do so on inspection and examination, and not on mere surmise; they are heartily welcome. I wish it to be tried and proved, and rejected if found wanting.

J. BARNES THOMPSON.

3, Rothwell-street, Regent's-park-road, N.W.,
4th October, 1864.

TELEGRAPHIC NEWS.

TELEGRAPHY IN THE HOLY LAND.—London is now in communication with Sidon and Jerusalem by the electric telegraph.

ATLANTIC TELEGRAPH COMPANY.—Her Majesty's sailing frigate, Amethyst, 26, attached to the reserve at Chatham, which has been lent by the Admiralty to the Atlantic Telegraph Company to receive on board the Atlantic telegraph cable, for conveyance to the Great Eastern steamship in the Medway, left Chatham harbour, early on the 5th inst., in tow of a private steamer, and without an Admiralty pilot, for the works of the company at Greenwich. There the first portion of the cable will be shipped, and conveyed to the Great Eastern. The consequence of allowing one of Her Majesty's ships to leave Chatham without the customary Queen's pilot on board, was that soon after the vessel had got clear of the harbour those in charge of her ran her ashore on one of the numerous shoals at Gillingham Reach, at the entrance to the harbour. No one in charge seemed to be aware of the intricacies of the navigation of the river at the spot, although these are perfectly familiar to the duly authorised Government pilots accustomed to the navigation of ships of war to and from Chatham. All attempts to tug the vessel off the bank on which she had grounded proved fruitless, and with a strong ebb tide under her bottom she soon settled down, straining herself, it is believed, very severely. At flood tide in the evening she was floated off, but the extent of the injury she has sustained, which it is hoped is not serious, cannot be fully ascertained until the frigate shall have been docked. The explanation given by the dockyard officials is, that the vessel, having been handed over for temporary use to the Telegraph Company, they had virtually no further control over her subsequent movements.—[The first disaster!—ED. *T. J.*]

The Overland Telegraph to America.—The royal mail steamer Scotia arrived at Liverpool on Saturday morning, the 1st instant, at 1.30. Among her passengers were Mr. Hiram Sibley, president of the Western Union Telegraph of America, and Mr. P. M'D. Collins, projector of the overland telegraph to America, viâ Behring's Straits, who are *en route* to St. Petersburg to carry out the enterprise. From later advices we learn that the Western Union Telegraph Company, who, in connection with the Russian Government, have this great enterprise in hand, are actively engaged in fitting out an expedition under the immediate supervision of Captain C. S. Bulkeley, of the United States army, for Oregon, the coast of Russian America, and the country lying beyond Behring's Straits, to survey the route of the telegraph line, and make all other needful arrangements for putting the whole extent of the line under contract the ensuing year, and we understand that the projectors of the enterprise are sanguine that the line will be in successful operation between New York, San Francisco, St. Petersburg, and London about the middle of 1866.

The Persian Gulf Telegraphic Cable.—From Cornhill to Calcutta by electric telegraph appears to be not far from realisation. The financial and commercial world will be gratified to learn that, according to advices from the East, there is every probability that the Persian Gulf telegraphic cable has by this time been placed in working order. At the last accounts, the rupture discovered to have taken place in shallow water was being promptly remedied. For the present, the intention of carrying a land-line from Bagdad to the Gulf, over exclusively Turkish territory, must be abandoned, owing to the absence of control on the part of the Turkish Pashalic Government over the wild tribes that inhabit it. The more circuitous Turco-Persian route would be available at the present moment but for the malaria during the season of the swampy lands bordering on the Tigris, and the accustomed display of Persian perversity in placing obstacles to a mutual arrangement for right of way over a small section of territory, the ownership of which it disputes with Turkey. This section could be run in a few days. Russian diplomacy, which has so long sought to frustrate our efforts in the East, is perhaps at the bottom of the difficulty—a difficulty, however, which is not insuperable, and which, owing to the conciliatory tone adopted by the Turkish Government, we may hope to see shortly removed. We cannot afford to have our communications with the East interrupted either by Persian perversity or Russian duplicity.—*Money Market Review.*

Gutta-percha.—The imports of this article have considerably increased this year, owing, doubtless, to the large consumption for submarine telegraphic cables in course of manufacture. Thus, in the eight months ending 31st August they amounted to 15,139 cwt., against 8,404 cwt. in the corresponding period of 1863, and 9,531 cwt. in the corresponding period of 1862. In August alone the imports were 3,444 cwt., against 750 cwt. in August, 1863, and 1,924 cwt. in August, 1862. In 1863 the total imports of this article were 21,655 cwt.; in 1862, 48,284 cwt.; in 1861, 19,749 cwt.; in 1860, 21,821 cwt.; in 1859, 18,598 cwt.; in 1858, 19,641 cwt.; in 1857, 17,420 cwt.; in 1856, 15,557 cwt.; in 1855, 28,585 cwt.; and in 1854, 24,606 cwt.

The First Railway Train into the City of London.—On the 6th inst. several of the directors of the London, Chatham, and Dover Railway, consisting of Lord Harris, deputy-chairman, Sir Cusack Roney, and Mr. Cobby, accompanied by Mr. Forbes, general manager, Messrs. Cubitt and Turner, the engineers of the company, Sir Morton Peto, and Messrs. Betts and Crampton, the contractors for the works, and other gentlemen, crossed over the bridge of the company for the first time, in a train from the Blackfriars Station to the intended new Ludgate Station. The bridge, as well as the engine, was gaily decorated with flags, and the numerous workmen engaged in the operations of the company cheered the train very heartily during its progress. It may be mentioned that this is the first railway train that has entered the City of London, for although the Farringdon Station of the Metropolitan Railway and the Fenchurch Station of the Blackwall line are the City termini of these companies, they are both situated outside the precints of the City proper. The train passed smoothly and easily along the line, and proceeded from the southern to the northern end of the bridge. The bridge consists of four lines of railway, but it was upon those of the western side that the train ran upon this occasion, the filling in of the other lines not being so far advanced. Messrs. Kennard Brothers, of Crumlin Iron Works, near Newport, Monmouthshire, were the contractors for the superstructure, and Mr. Friend French, the practical engineer over the whole of the works. A new feature in this bridge, when altogether finished, will be that, along the top of the cross, elliptical braces on both lines of railway, 20 lines of telegraphic wire on each side will be fixed, making 40 in the width of the 56 feet; thus making a kind of curve over-head, which will have a very pretty and unique appearance. The examination throughout was deemed perfectly satisfactory. It is expected that the Ludgate-hill Station of the London, Chatham, and Dover Company will be opened for traffic to the public the latter end of next month.

South Australian Telegraphs.—We quote the following from the *South Australian Register*:—Mr. Todd states in his annual report, which has recently been laid before Parliament, that there is little probability of any steps being taken for the realisation of the proposal to establish telegraphic communication between Australia and England until the Indian line has been completed and thoroughly tested, for it would be altogether premature to enter into arrangements at this end of the Anglo-Australian line before the other end was in working order. Since Mr. Todd's report was written, however, suggestions have been laid before the authorities by a gentlemen of much experience who is now in Adelaide, relative to the advisability of establishing an overland telegraph between this colony and the northern settlement, with the view of bringing the several Australian communities nearer to the main postal route of India, China, and Europe. The idea is that a company should be formed for this purpose, and that, in addition to the opening of telegraphic communication with Van Diemen's Gulf, they should establish a line of small but fast steamers, one of which should leave Singapore for North Australia immediately after the arrival of each mail steamer from Suez, whether British or French. The preliminary operations of such a company, it is stated, would consist in establishing stations at distances of from twenty-five to fifty miles along the route explored by Mr. Stuart, which stations would be used for the purposes of the telegraph line and also for the maintenance of a horse post, which it is thought might be at first used for the transmission of mails. "By this arrangement," it is said, "regular postal communication would be established three times a month with Singapore, one of the chief ports and depots of the great steam line from Suez to China and Japan, and whence independent lines diverge to all the important European settlements on the Asiatic coasts and islands, namely—two to Bombay, three to Calcutta (one of which touches at the intermediate ports on the east side of Bengal), one to Siam, one to Cochin-China, five to China, one to Borneo, and two to Batavia, one of which continues the communication to all the Dutch ports of the Indian Archipelago." By the establishment, then, of an overland line of communication with steamers at the other end, all these ports and country would be brought into direct communication with the Australian colonies. It is stated that with a horse-post to North Australia, and steamers from Van Dieman's Gulf to Singapore, the transit would be sixteen and a-half days—the overland route from Adelaide being 1,400 miles, and the sea voyage 1,860 miles. These sixteen and a-half days added to the time which it would take to convey the mails from Point de Galle to Singapore would make about twenty-two or twenty-three days, or rather more than the time occupied by the Peninsular and Oriental steamer, via King George's Sound. There would, therefore, appear to be no advantage offered by the proposed communication overland as regards time, whilst the bulk of the mails would still have to be conveyed by sea. But, it is said, "the continuation of the European telegraph line to Singapore, which the Home Government are pledged to carry out as soon as the line is completed, would admit of six or seven days' later news being sent by post overland than can be obtained by the steamer which sails from Ceylon; and as it would be desirable to commence the North Australian line at the Adelaide end, each section as completed would be available for the transmission of intelligence; so that the new enterprise would compete successfully with the old route from the very first." It is, however, chiefly with regard to the operations of the telegraphic line when completed that the attention of the Australian colonies is called to this project. The following suggestions as to the capital which a company would require are extracted from the memorandum which we have referred to:—"The cost of the telegraph line will be £138 per mile, or £193,200 for the whole. Three steamers, which need not be of greater burden than 100 tons each, will suffice to keep up the communication with Singapore, but a fourth may be needed in case of accident. The cost of these will be about £5,000 each, or £20,000 in all. The cost of forming stations is included in the estimate for the telegraph line. The cost of a set of horses and gear will be about £2,500; bullocks and drays about £1,000. The annual expenditure in wages, coals, stores, &c., need not be estimated at present, but it may reasonably be calculated that telegraph fees and a subsidy from Government, in lieu of postage fees, will not only cover all this, but leave a large surplus. The cordial support of the general public, not only of this province but of the colonies generally, may be looked for with confidence. Certainly Victoria will approve of it, and probably New South Wales also. But this colony will be most benefited. The whole expenditure, with the exception of a portion of the outlay on steamers, will be disbursed within the limits of the province, and the impulse thus given to colonial enterprise must be felt by every member of the community. Under these circumstances a guarantee of say 5 per cent. on the paid-up capital is not likely to be withheld. The capital should be not less than £250,000; the Government guarantee on this would be £12,500 per annum. The monthly steamer to King George's Sound costs nearly £17,000 per annum at the present time." We do not understand, however, that this overland communication could for a great length of time be used as a safe substitute for the mail service by way of King George's Sound. It might supplement that service in a valuable manner, and also by means of telegraph wires insure the Australian colonies later news than can be obtained by steamers. This alone is a matter of undoubted importance, and deserves the consideration of all the colonists. Our readers may feel, perhaps, that the time is hardly come for entering upon such an enterprise. Nevertheless, the facts set forth are full of interest, and cannot be otherwise than useful, as they have been arrived at after careful inquiry as well as long experience in North Australia and the adjacent countries. We published a few days since a letter from Dr. Embling, of Victoria, relative to the practicability of establishing a regular overland communication between North Australia and South Australia. This gentleman has seen some reference in the public papers to suggestions which have been made in this colony on the subject of postal and telegraphic communication with the opposite side of the continent, and has taken the opportunity to express the strong opinions which he has been long known to entertain in favour of such a work, as well as to recommend that, in the

event of any steps being taken for this purpose, the Government of Victoria should be applied to for their co-operation and assistance. Dr. Embling states that some of the camels which were imported for the use of the unfortunate Victorian expedition, and which did their work well, are now located on the Wimmera; and he advises that whenever they are wanted they should be obtained, and be used either in establishing an overland postal communication, or in assisting to construct a line of telegraph between these colonies and the opposite coast. It is probable that the public mind will have to be prepared by a great deal of discussion on this subject before the work of constructing tramways and telegraphs through the centre of Australia is really entered upon. The distance is so great, the difficulties of the overland route are said to be so considerable, and the experiment of colonizing the opposite coast is so much in its infancy, that most persons will regard the question of tramways and telegraphs as one that at present can only be talked about. But even supposing the objections to be so great as they have been represented to be, it is still desirable that this matter should be discussed as early and as fully as possible. We all know by experience how often the extreme views of to-day become the practical realization of to-morrow; and in reference to the present subject, we feel certain that population alone is required to make it absolutely necessary that the northern and the southern coasts of this continent should be connected by complete and effective means of communication. A telegraph through the centre of Australia would be but a trifling work compared to the vast lines which have been established in other countries. We may mention, for instance, the telegraph which the Americans have constructed across the Rocky Mountains, and which now joins New York to San Francisco—the Atlantic to the Pacific. But though some time may elapse before Dr. Embling's cherished hopes are fully realized, there are strong reasons why steps should be taken at an early date to test the practicability of establishing a communication by means of camels between this colony and North Australia. At present there is some degree of uncertainty as to the general availability of the overland route. The points at which water my be found are not satisfactorily known; and and, interesting as Mr. Stuart's diary is, there are still many matters relative to the character of the country which are not there touched upon. If, then, the experiment which is now being tried at Van Diemen's Gulf should turn out to be a success, it will be necessary to thoroughly examine the overland route; and this is a work for which the Victorian camels would be admirably adapted. With regard to the question of introducing these animals for travelling in the North, it is a matter of surprise that they have not already been more generally used. Mr. Howitt gave a favourable account of those that were employed in the Burke Relief Expedition. Mr. M'Kinlay, too, spoke in high terms of the camels which formed a part of his expedition. Their valuable services are referred to in various parts of that explorer's journal, and especially in that part which describes the difficulties which were experienced in the flooded country beyond the Stony Desert, where, it is said, the camels were as useful as boats; for when everything else was under water their backs were high and dry, We trust, then, that in any future attempt at opening the interior of the continent, Dr. Embling's suggestion will be acted upon, and that the camels in Victoria will be utilised. He states that the best of them would travel 800 miles, each carrying a man and a letter-bag, in seven days. At some no distant date we have every reason to believe that these animals will be generally used in Australia. The "Camel Carrying Company," that was sought to be established in Adelaide a few years ago, was a failure because its promoters had no fixed idea of what they intended to do; but since that time camels have been fairly tried in Australian exploration, and the experiment has been a complete success. The main part of the scheme, however, which has attracted Dr. Embling's attention, and which is well deserving of consideration, is that the Australian colonies should construct a telegraph line to the northern coast without waiting until the Anglo-Indian line can be extended across the sea to Van Diemen's Gulf. It may be a very long time before this can be accomplished; but it is said that without such a submarine line the colonies might at once place themselves much nearer to England than they are at the present time. It has been pointed out that, with an overland telegraph and with steam communication between North Australia and Singapore, we might receive English news a fortnight later than any which can be brought on board the steamers by way of Ceylon and King George's Sound. With regard to the cost of such an undertaking, the estimate which has been made is as follows:—Overland telegraph, £193,200, at £138 per mile, and four steamers, at £5,000 each, £20,000. But the idea is that the scheme should include means of transit for mails, so that further expenditure would be necessary to provide horses or camels. Altogether the subject is one which the Australian colonies cannot but feel an interest in, and which will force itself upon public attention at a very early date if the colonization of the northern coast should be attended with success.

Conduction of Heat.—In relation to Tyndal's researches, M. l'Abbé Laborde states that he has heated to redness one end of a thin iron bar so long that the other end could be held without burning. When the red end was plunged into water the other end became so hot that he was compelled to drop it. The rapid compression of the hot metal, he says, is no doubt the cause of the elevation of temperature; but he asks if another cause may not be suspected—for instance, the creation of thermo-electric currents. For this purpose he made a rather rough experiment, which is described in *Les Mondes*, Vol. IV., No. 1.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2362. W. Clark, improvements in the means of actuating electric dials or clocks.—A communication.

2388. C. W. Allen, new or improved arrangements or mechanism for communicating between any passenger and the guard and engine-driver of a railway train.

2423. F. N. Gisborne, improvements in the means of working electric signals for gunnery practice.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2218. A. A. Davis, improvements in apparatus for communicating or signalling between the guard and driver and between the passengers and guard or driver of railway trains.

2255. R. T. Hall, improvements in the means of communicating between passengers and guards in railway trains.

2307. C. W. Howell, improved means or apparatus for communicating from the passengers or driver to the guard of a railway train.

PATENTS SEALED.

821. J. Hunt, an improved instrument, or "tell tale," for registering the time of arrival and departure of workpeople in houses of business and manufactories.

819. J. B. Thompson, improvements in electro-magnetic induction machines.

NOTICE TO PROCEED.

1298. W. Passmore, making sewing-machine, rotary hair-brushing machines, electrical apparatus, and lathes, self acting.

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

2464. W. T. Henley, improvements in magnetic and electric telegraph apparatus, which are also applicable to other purposes.—3rd October, 1861.

MAGNESIUM AND ITS LIGHT.

DR. LIVINGSTONE, Bishop Colenso, and Magnesium, were three of the chief popular attractions at the recent meeting of the British Association in Bath. Professor Roscoe, at his lecture on light, in the theatre, had a table covered with specimens of magnesium, crude, purified by distillation, and in wire. Taking in his hand a lump of distilled metal, nine pounds in weight and about the size of a man's hat, he presented it to his audience as an evidence of the progress made within a few years, before which magnesium was only known impure and in grains, and preserved as a rarity ~~in a few laboratories~~. For this progress the world is indebted to Mr. Edward Sonstadt. About the beginning of 1861 he attacked the problem of the commercial production of magnesium. After many and prolonged pains and countless and costly experiments, his efforts were rewarded with success. In 1863 he presented the Royal Institution with a fine lump of the distilled metal; and in the present year he has been favoured to see a "Magnesium Metal Company, Limited," established in Manchester to work his patents, and who advertise themselves as ready to supply magnesium in any quantity for which there may be a demand.

The first use to which magnesium has been applied is, as a source of light. Its value as an illuminator had been foreseen ere Mr. Sonstadt set to work. Professor Roscoe, in 1859, indicated the fact, and a commission under the Austrian government verified by experiment its prodigious light-giving power, and only on the score of expense, and with regret, set aside its employment as impracticable—a reason which has now ceased to exist. In the Bath theatre Professor Roscoe stated that "a burning magnesium wire of the thickness of ·297 millimetre evolves as much light as 74 stearine candles, of which five go to the pound. If this light lasted one minute, ·987 metre of wire, weighing ·120 grammes, would be burnt. In order to produce a light equal to 74 stearine candles, burning for ten hours, whereby about 20 lbs. of stearine is consumed, 72·2 grammes (2½ ounces) of magnesium would be required." Practical evidence on this head he quickly adduced. Two lamps with large reflectors, in which coils of magnesium wire were paid out by hand as they burned, were lighted. In an instant the house was flooded with a rich white light, as soft as brilliant, in which the colours of the ladies' dresses and the bloom of their complexions were displayed as naturally as in daylight. All eyes kept wandering over the scene in order to enjoy the novel and delightful effect. When at last the magnesium lamps were extinguished, the gas lights, which had been overpowered by their superior radiance, seemed changed by contrast into farthing dips, yielding a dim, sickly, and dirty yellow illumination. In proof the richness of magnesium light in actinic or chemical rays, Sir Charles Lyell was called forth and his photograph taken on the spot by means of two or three bits of burning magnesium wire waved about while held in wooden clips; and shortly, an excellent likeness of the prince of geologists was magnified and thrown on a screen by the magic lantern amid the loud applause of the assembly. At the close of Professor Roscoe's lecture, Mr. Ladd exhibited an electric light, derived from 60 cells of a Grove's battery, when a gentleman stepped forth and held alongside two burning magnesium wires twisted together. The intensity of the electric light was manifest, but the magnesium light did not suffer by the comparison, and considering the simple and impromptu means by which it was obtained, its practical value was most effectively demonstrated.

This exhibition of magnesium by Professor Roscoe excited much interest, and the shop of an enterprising chemist in Bath, who advertised "Magnesium wire for burning, 3*d*, per foot," was day after day thronged with purchasers. It seemed the general opinion that photography would receive a new extension from the magnesium light. Caves, mines, catacombs, and the interiors of the pyramids could now be revealed in myriads of pictures. The photographer would now be enabled to pursue his calling under the gloomiest or the smokiest sky; and very probably he would be called upon to devote his evenings to his art—the time when busy people especially are most at leisure to sit for their portraits. Photographs of Sir Henry Holland, Professors Faraday and Roscoe, and other celebrities, taken at night by the magnesium light, were freely handed about, and except for the inscription, no one could have detected a difference between them and the best work of the sun himself.

Apart from photography it was very plain that in magnesium a new signal light was discovered, which, for handiness at least, set the lime and electric lights at defiance—any one with a bit of magnesium wire and a lucifer match can in an instant produce a light which may be discerned miles off: indeed, the light has been plainly discerned at a distance of twenty-eight miles at sea; how much further remains to be determined. In rockets and fire-works the filings of magnesium scintillate with a dazzling, far-reaching and unequalled power. Already several Governments have taken magnesium in hand and are diligently prosecuting experiments, which, if satisfactory, will result in magnesium being entered as a stock commodity in all their arsenals. Theatrical managers are also experimenting with a view to new sensations in Christmas pantomimes and Easter pieces. Surgeons find the light highly convenient in examinations with the speculum; and chemists discover a hundred uses for it in the laboratory. It is said, some shopkeepers will astonish the Londoners with the light in the course of the winter. Already two patents have been taken out for magnesium lamps, and others are promised. The purposes to which the light may be applied are manifold and every month reveals new ones. Some gentlemen at Bath drew unfavourable inferences against the extensive use of the metal from the high price of the wire, but, if we are not misinformed, 3*d*. per foot is merely a provisional and experimental figure. Whenever there arises a fixed and calculable demand, quite a different price will be quoted. As everybody with any commercial experience may know, price is governed by the scale of production. If iron were wrought on the same scale as is magnesium at present, we question whether iron wire could be vended retail at 3*d*. per foot.

As chemists are aware, magnesium is one of the most abundant metals in Nature. Besides entering into the composition of a large number and variety of less abundant minerals, it constitutes 13 or 14 per cent. of dolomite or magnesian limestone, a rock which is found in almost all parts of the world in enormous quantity. In England, for example, the magnesian limestone formation extends from Tynemouth to Nottingham, a distance of 147 miles, and over at least part of that long line is fully 600 feet thick. Magnesian limestone consists partly of carbonate of magnesium and partly of carbonate of calcium; but carbonate of magnesium by itself exists in immense masses

in some parts of the world, as, for instance, in Greece and in India. In the ocean, moreover, magnesium exists in such quantity that Mr. Sonstadt has calculated that it contains 160,000 cubic miles of the metal,—a mass so great that it would cover the entire surface of the globe, both sea and land, to a thickness of more than eight feet.

Sir Humphrey Davy, in 1807, first revealed the existence of magnesium; but nearly half a century elapsed ere a Sonstadt was found to throw wide the doors to the vast treasure-houses wherein it lay stored. Human nature will be changed indeed if these doors now open should ever again be closed. Not only one of the most abundant metals, magnesium is among the most beautiful. When thoroughly pure, it is as white as silver, readily receives a high polish, and is easily kept clean. Moreover it is very light, its specific gravity being 1·74, or less than a fifth the weight of copper, and almost half that of aluminium, which is 2·60, and until the appearance of magnesium considered a marvel of lightness. An ounce of magnesium and an ounce of silver represent very different bulks. At present, many of the peculiarities of magnesium are undetermined; like all other metals it has a character and oddities of its own which will only become intelligible after multiplied experience. In some cases it shows itself very brittle; in others tough as steel: one manufacturer trying his hand at a magnesium button found his material fly into fragments under pressure, whilst Mr. Conningsby, of the Crystal Palace, struck a medal with ease and perfect success. To what uses, in addition to burning as a light, magnesium will be applied, it would be idle to speculate: time and trial alone can make manifest; but we think that we may safely predict that in the appearance of this metal we behold a new agent of civilization—one which will write a broad line on the world's future.

REMARKS ON CAPTAIN MAURY'S AND M. MARIE DAVY'S LETTERS RESPECTING METEOROLOGIC TELEGRAPHY.

By Admiral FitzRoy, F.R.S.

Having read in the *Courrier des Sciences*, and in the *Bulletin International*, published at Paris, a letter from the celebrated Maury respecting meteorologic telegraphy, in which he gives certain views the importance due to his authority; and as their tendency is not of a *progressive* character—owing, perhaps, to his own able mind having lately been unavoidably engrossed by lamentable internecine war—it appears to me a duty, considering the public interests affected, to comment briefly on my friend's letter.

Captain Maury, like many other really competent and authoritative judges of various scientific questions, has not had time, means, or inclination to study the daily complications and published facts of atmospheric changes.

It is only at such centres of communication and continuous reference as Berlin, Paris, or London that deductions can be drawn satisfactorily, after years of experience.

Not only are telegraphic correspondents at distant stations, in considerable number, indispensable, but the collection and collation of accounts, or descriptions of weather, in as many places as may afford them, must be practicable speedily.

No private individual, unassisted by public aid, can have such machinery, and therefore his opinion of the systems in operation cannot be so valuable as the prestige of his name might lead the public to suppose.

For example, in this office records or data have been gathered and considered during ten years unintermittingly. My assistant, Mr. Babington, has incessantly devoted his chief attention to the constitution and dynametry of the atmosphere, not over Europe and the Atlantic only, but the whole world. We act on the same principles, and it is now absolutely a matter of indifference whether he or I draw the forecasts of weather, or send out cautionary signals.

This *could* not be without a definite system on a truly scientific basis.

At Berlin the esteemed Professor Dové, with thirty years of European reputation, has had accurate and extensive information for many years; while at Paris—excellent centre of continental communication and great telegraphic combination—the eminent astronomer and senator, Le Verrier, well aided in meteorology by a learned electrician and physician, Marié Davy, have vast advantages in considering and treating meteorologic questions.

While these centres of opinion—aided by maritime reports, such as the *Moniteur de la Flotte*, the *Shipping and Mercantile Gazette*, and numerous local publications—have the means of comparing, checking, and duly considering each day's forecast (prévision), and the weather actually occurring afterwards, advantageous sources of opinion are available to which no individual can lay just claim.

In corroboration of what has been said about the general value of forecasts, as applicable to a *range* of coast and *prevailing* direct wind, not specifically to *confined* localities or mere eddy winds, I may refer you to Captain Mouchez, my esteemed colleague in meteorology, at the Ministry of Marine in Paris.

Having premised thus much, allow me to say that, in discouraging such forecasts as are now drawn in France and England, Captain Maury is unaware how completely he would destroy the scientific foundation of telegraphic *cautionary* notices (often, but less correctly, called "storm warnings").

Only in consequence of attentive and incessant study of atmospheric dynamics, as well as certain statical facts, after a due apprenticeship (so to speak) to the very comprehensive subject, can adequate skill be attained in acting with these recently combined atoms of experimental knowledge. Like the not distantly related practical science of magnetism applied to compasses in iron ships, it has yet only a few votaries, its intricacies and necessarily prolonged study not attracting some modern philosophers who would grasp all manner of subjects, although hardly able to realise mentally half the varying conditions of air and ocean. It is supposed by many that forecasts of weather and their occasional results—advertisement of strong wind, or, it may be, warning of a tempest—depend only on notices sent from distant places at which a storm has begun. Nothing can now be more fallacious. True it is that in 1861 we began with the belief that by such aid we might do so. But advances have been made day by day; and during the last year or more cautionary notices have often been sent by telegraph to the farthest stations, even most toward the coming storm (or to windward of us), in good time to warn them of the preparation necessary to be made in an exposed seaport, such as Valencia or Aberdeen. As I have said elsewhere on this naturally, and *very* properly *disputed* question, facts are as the ground, telegraph wires are roots, a central office is the trunk, forecasts are branches, and cautionary signals are as fruits of this youngest tree of knowledge.

Permit me now to turn for an instant to some special facts, too little known even to one so well informed generally as the sagacious Maury.

In the zones of the world usually called temperate true east winds are so rare that they become quite exceptional. What we call in general parlance easterly, or east winds, are polar currents, more or less deflected by meeting opposition of air or land.

In these zones the atmosphere has a general progression toward the east. Storms, or vast eddies between great breadths of mutually antagonistic currents of air, are therefore carried along (translated) toward the east (more or less deflected by local conditions toward the north or south), and having passed the meridian of any place, are *gone*—excepting their rearward effects—as far as the places under that meridian are concerned. Such storms may not, however, reach very far in a meridional direction, although travelling eastward during *two or three days* on rare occasions. Hence it is obvious that in temperate zones stations for special warning stations are required north, west, and south of a centre, but not toward the east, except for general information, and to be themselves warned.

Ask the learned and most experienced Quêtélet, who so satisfactorily presided over the Brussels Meteorologic Conference in 1853, whether he ever has observed any continuance of true east wind in Belgium, or inquire from any person of experience, at sea especially, whether the so-called east wind is not a north-easter or a south-easter while in *force*.

In this country, as in America, some *misquote* the lamented Espy (who said the wind blew from places of high barometer toward those of low pressure), by ascribing to him a most unmathematical corollary, that all gales are "straight lined," and that cyclonic circuits are "fallacies." Such persons surely betray themselves. Air moving from various spaces of high tension toward a limited area of *depression* must meet, and have a tendency to gyrate, being

unable to go far upward on account of gravity. Any such upward determination must tend, however, by its overflow to augment the tension or pressure about the outer portions of any such circuit.

We find here that the main currents, polar and tropical, have very different electric characteristics—one, the polar, being always plus; the other always minus, if pure (unmixed with the polar).

We also have found the telegraph wires much disturbed when these main (principal) currents were beginning to act positively in force. No great tempest, no heavy polar or tropical gale has occurred here since 1860, without more or less "*wire disturbance*" (as the telegraphists say), and I am led by these, with other concomitant facts, and examination of numerous sea records, as well as registers on land, to believe that such electric effects are caused by atmospheric collision, and that "*magnetic storms*," sedulously watched now at many observatories, are *results* of atmospheric storms, somewhere in one hemisphere or the other, instantaneously felt through air, however remote—either by conduction or by vibration—as an earthquake is felt on board ship in the middle of a deep ocean, even the South Pacific.

In the *Bulletin International* of the 12th instant M. Marié Davy asked, "*A quelle cause devons nous attribuer ces grands tourbillonnements de l'air?*"

Having particularly studied this interesting branch of atmospheric dynametry, and trusting to authorities like Sir John Herschel, Professor Dové, and others, during whose lives meteorology has been one of their pursuits, I will venture to offer a few observations.

Assuming that Hadley's and Halley's original hypotheses are sufficiently supported by the best subsequent authorities, and definitively proved by recurrence of accumulated facts, by adding to *their* views Dové's "parallel currents" and "gyrations" of wind, besides Herschel's "antitrades," we are enabled to advance at once into details, easy *now* to trace out and connect.

Without adverting here to views circulated from the Board of Trade since 1855, it will suffice to say that certain *periodic* effects of temperature and of *gravitation* have been traced by facts, whence the following *four* inductions seem warranted.

First—A very small tidal effect, caused semi-diurnally by solar influence, and felt (meridionally) about the torrid and tropical zones.

Second—A solar tide, however small, due to gravitation, and only evident by its dynamic effects *horizontally*.

Third—A lunar tidal action, not evidenced vertically but *laterally*, and with *force*.

Fourth—A *mutual* attraction and consequent tendency (not unlike the effect of induced magnetism) between contiguous volumes of air, which occasions more or less adhesion (or resistance to separation) when they move, and a certain friction that may have *any* degree of force, from the gentlest movement *of a light breath to the escape of steam from a boiler into cool air, developing electricity* (as seen experimentally at the Polytechnic). Now these results (facts accordant to philosophic principles), when combined with previous generalizations in their application, may be found adequate to solve many interesting, but hitherto obscure, problems in meteorologic dynametry, those especially which have immediate reference to practical *forecasting* of the *weather*.

The first is familiarly known to meteorologists as depending on the sun's position, and being regular to an hour or two, though not recurring exactly (as said by some) in *all* intertropic places, because occasionally affected by peculiar local conditions, such as high mountains, arid deserts, heavy continuous rain, or by storms.

The second effect of solar attraction is shown by the differences between syzygial and intermediate results, observed in connection with those of the moon's action.

The third and by far the most important disturbing cause, next to *heat and cold*, appears to be lunar attraction. But this effect of gravity is not *apparent*—like oceanic tides. Oceans are intersected by land; water is an inelastic fluid; a tidal impulse is not soon checked—the ocean *in mass* seeks equilibrium;—after disturbance it reverts, and with acquired momentum does more than restore itself to position—it advances *eastward* and then again *recoils* from its eastern boundary.

Air, our atmospheric enclosure, from 10 to 15 miles in depth, (practically considered), is free to move in *any* direction,—excepting against a few high ranges of mountains such as the Himalayas and Andes, which an *average*, are not three miles high, and do not extend through *many* degrees (*meridionally*) at their highest elevation; although a few peaks attain four or five miles in measured altitude.

The combined effect of moon and sun, or the "*luni-solar*" action of gravity on this *outer* atmosphere, has a tendency to draw it toward and after those bodies, as the earth turns eastward, whence motion, as of a perennial current, might be caused, did not "*ante-attraction*" (anterior effect on the mass *approached*) and centrifugal impulse of rotation, act in a contrary direction.

Antagonistic forces being thus nearly balanced in effects, no important longitudinal or equatorial, or east to west movement of fluid air exists; but the *waves* raised and *upheld* (by sun or moon, or by both *together* at syzygy), *under* which has been an indraft, with momentum—are constrained to subside by *overflow*—running off in horizontal currents *meridionally*.

While so *lifted*, upheld by moon's or sun's attraction (however much above normal elevation) very little tension or sensible pressure on a barometer differing from that read off a few hours sooner or later would be noticed, because the earth's attraction diminishes as that of the luminary increases; and there would be no *other* reasons, *usually*, for barometric effects, of much comparative moment.

In those regions there would be no mutual *antagonism or over-running* of air currents, no condensing body of cold dry polar air acting, as in temperate zones.

Not *long*, however, does *upper* air retain a *meridional* direction, whether maintaining its *equatorial* velocity, for a time,—and therefore moving more and more toward east, as meridians converge—or only impelled, by *tendency to equilibrium*, toward the polar regions —whence air is incessantly drawn that must be replaced.

In considering luni-solar attraction—the *difference* between vertical action and tangential, that on the torrid zone, and at the poles (so dissimilar in their *directions* and in their *effects*), should be carefully considered—one being *direct* the other as it were *glancing*.

High mountains and clouds crossing stars afford the most direct evidence in *low* latitudes of *upper* currents occasioned by luni-solar action. They are always seen in the tropics. Their variations and *periodicities* of effect have been observed to correspond nearly with lunar *intervals* (not *usually*, though sometimes, with the *phases*).

Hence ample causes exist for variations in force and regularity of upper, returning, or tropical currents of air, which must occasion many consequent irregularities in the lower advancing, or polar winds, even in low latitudes; but vastly more in the temperate zones, where other circumstances operate, and *variously*.

Volumes of tropical air, from around the whole world, thus pressing from every direction along, or across, converging meridians toward the poles—occasion incessant *antagonism* from polar currents in the middle and higher latitudes, but especially in the temperate zones.

Instead of passing *over* these advancing breadths of atmosphere the winds from tropical zones, when near middle latitudes, *usually* move along earth's or ocean's surface more or less interrupted, intermixed with, opposed or displaced by, occasional polar winds; —and the collision of these incessantly antagonistic currents—at variance in quality and quantity, as well as in direction—is proved to be the cause not only of our storms, but of all minor changes, and of their *ordinary*, more or less rotary (rather indeed *semi-rotary*) effects, as commonly witnessed.

When two currents are passing in opposite or different directions —each acts on the other—and between them (if both move) is a *comparatively* neutral space. Unless very forcibly pressed together —by lateral, cross, or *wedging* action—each current yields, in some degree, to the other—(elastic air much more than water). If one be moving (say) to south-west—the other toward north-east—each some hundred miles in width (however shallow) there will probably be a space of very many miles between them, in which the wind will change from one point to the other, through a semicircle, or other curve, gradually (if *moderate*), and thus an appearance of turning, semi-rotation, or gyration of wind, is caused, at any station, in a simple manner, irrespective *of earth's motion*. Through the *next* current of air, *direction* of wind remains steady or nearly so, until the western edge approaches, when a similar *half turn* commences, which, with the former, completes a gyration, when the other stream, or current, attains the place of observation, not usually by direct, but by *lateral* progression (as they move eastward with the whole mass of atmosphere in that zone).

As the *highest* barometer and *lowest* temperature are about midway in the polar current—the lowest or least tension, with the warmest air, being near the middle of each tropical current—it is natural that tabular co-ordination, in curves, on a diagram, should have induced ideas of "*atmospheric waves*," moving from north-west to south-east.

When antagonistic or even crossing currents act *impulsively* against each other—forcibly, and with momentum—more than half a turn—even a cyclone is caused. If violently, and its *causing currents persist*, such a cyclone may last two or three days, and be carried on eastward between its originating currents.

Observations have shown that impulses or "*pulsations*" extend from tropical latitudes toward the poles; that they are resisted and divided into *currents* unequal, irregular, and diverging (as it were) projected like tongues, streams, or shoots, from broad tropical impulsions, which sometimes advance like immensely wide "bores" (of rivers) causing great commotions, such as storms, cyclones, gales, or squalls, along their *front*, and between the *streams* sent on in advance some hundred miles, more or less. The alignment of the front of such an impulsion (tropical "*downrush*" of Herschel) is north-west and south-east, nearly (if not altered by land).

As thus impelled with great momentum outshoots advance, and alternating volumes or streams of polar wind, are met;—by which collisions, squalls, semirotary, or even cyclonic, are caused—tension is raised by mechanical resistance—temperature is affected, and storms often follow.

Such movements occurred on a *great scale*—early last December, when a tempestuous space extended from the Atlantic to Italy, and some observers thought that one and the same storm, even the *same cyclone*, traversed Europe from Ireland to Rome, in little more than 24 hours,—therefore imagining that the *centre* of the storm moved about fifty miles an hour; with which the wind's velocity at one part of the gyration must then have been about 130 miles an hour *continuously*.

Such a view requires the progress of that storm to have been from the north-west toward the south-east, which our charts show did *not occur*.

It travelled, as usual, *toward north-east*, while *other* rotary or semi-rotary storms were occurring in the south of France and in Italy,—all within two or three days of each other, between the Atlantic and Adriatic commotions — but *different* disturbances, occasioned by the same great tropical action against Arctic cold atmosphere.

Usually such tropical impulses seem to divide or branch off into currents—as any resisted water-wave impels streams onward horizontally, which separately intermingle with other *resisting* fluid, at rest or moving antagonistically.

To produce a *complete* cyclone there must be *great forces* engaged, in order to cause sufficient impulse, with momentum, for entire and *continued* rotation.

Many, if not most of the gales, supposed to be *cyclones* (in *one side* of which the observer *seemed* to be) are believed by the present writer to have been such *semi-rotary* effects of adjacent currents, in antagonism, as have now been described.

All the effects of gyration, or rotary change, may be explained by consideration of currents moving *variously, while all are uniformly translated* toward the east in the temperate, but toward the west in the torrid zone.

In connection with these subjects a few remarks on the *Bulletin International* may be not entirely out of place, or unacceptable, it is hoped.

Since the first appearance of meteorologic charts *last summer* (in that valued daily publication), attention has naturally been drawn to the marked isobarometric curves, which seem indicative of such combinations of movements as have been outlined in this paper, intermixtures of advanced tension in a *south-west* to a *north-east* direction, and parallel breadths or bands of alternate high and low tension in similar *lines*, *sectional* diagrams of which have a wave-like curve, which shows the greatest *apparent* undulations in a *north-west* to *south-east* direction—whence a double curve or intersection.

Neither isobarometric *curves*, nor any kind of wave or *crest lines*, seem to show *directions* of wind.

How can they? Winds being dynamic *currents*, occasioned by differences of atmospheric conditions, tensions, and temperatures—while lines of approximately equal tension are *statical* positions, showing quantities, or amounts (but not directions), whence the varied *dynamic* consequences are derived.

But they might be shown by *other directional lines*.

We have heard and read a good deal about "atmospheric waves," and winds supposed to be their *consequences*, but I have not yet been so fortunate as to discover any author's illustrations of the *practical manner* in which a wave (supposed) from north-west does occasion a south-west or a north-east storm. The mechanical action, the horizontal (or other) motions of fluid air, in volumes, zones, or bands, have not been traced out, or followed satisfactorily. Yet they must be the basis of practical meteorology.

Not irrelevant to these atmospheric questions, and a subject of extreme interest to speculative meteorologists, is the problematic uncertainty respecting our atmosphere's extreme periphery.

Poisson, in his "Treatise on Heat," assumed that the excessive cold of space has a condensing effect on air, causing it to become viscous; and a very eminent mathematician lately wrote to me, saying, that he inclined to a similar view, if not to a belief in its actual *congelation*.*—*Frozen air* around our atmosphere! *Is there air*, or only the lightest of all gases beyond our *sensible* atmosphere? How would centrifugal force affect air in a comparatively solid state? How would transmission and refraction of light be affected? What effects would there be on heat—on tides of air, and on the passage of *meteorites* (if extra mundane in origin)?

These and other great difficulties appear to be in direct opposition to such theories; however eminent the mathematicians may have been by whom they were supported.

There may be a less involved and difficult explanation of this subject (a solution, possibly, of the chief questions) attainable by careful consideration of the dynametry of air, or water, displaced by a solid body moving through either—and by expanding the simile, infinitely.

As a ship passes through water a certain quantity of fluid almost adheres to the solid body, and is drawn along, by induced or cohesive attraction, causing some friction. Close adjacent to this slight, even *film*-like quantity, the fluid has less impetus *along with* the ship, and still less as distance increases,—the practical result being that a band, or ribbon-like strip of fluid is drawn onward by and with the ship—actually following after in the wake.

Disturbance caused by the ship's motion affects a certain extent of circumambient fluid, but less and less, as distance from the motor augments, until destroyed by resistance.

May we not imagine that a somewhat similar process is in operation, however vastly grander the scale, around our world? The whole depth or body of atmosphere (*sensibly* ten miles, or thereabout) may be carried on, and around with earth, as a band of water is drawn along by a moving ship; the extreme exterior portion, above the highest mountains, having a gradual inclination more or more *westward*, till lost, as to matter and motion, in the immensity of space?

Either a *gradual* diminution of such a kind as this must take place, or a *definite limit* of material fluid, air, or gas must be imagined.

And such a *material* limit would demand some kind of demarcation in extent, with relation to effects of centrifugal force, and much more consideration respecting its bearings on light, heat, and their correlatives, than have been applied to our atmosphere, on a supposition of gradual attenuation without definable limit.

THE INDO-EUROPEAN TELEGRAPH.

The *Levant Herald* of the 21st and 28th ultimo furnishes the following particulars of this important line, which, we are assured by our correspondent at Constantinople, may be relied upon:—

Accurate information with respect to the Anglo-Indian telegraph is, we know, eagerly desired in Europe. The benefits, international and commercial, which would accrue from the completion of this undertaking are so remarkable and manifest, that their repetition would be like the reiteration of a thrice-told tale. The rupture of the Persian Gulf cable, the disturbances in the Montefik district near Bagdad, and the general undefined rumours which are floating about, have left the vague impression upon public mind that all is not going on well with this great international enterprise. The best way to correct these hazy notions, and to lay before the public the actually existing state of things, is to describe in a few words what the circumstances precisely are. Communication from India to Europe—from Calcutta to London—the realization almost of an *Arabian Night's* dream—will be accomplished, in the main, through the submarine cable laid down in the Persian Gulf, and two land lines from Bagdad, one through exclusively Turkish territory by way of Montefik, and the other by a more circuitous route through Persia, converging eventually at Constantinople, and thus becoming connected with the general European network of telegraphic inter-

* Sir John Lubbock, Bart., F.R.S.

course. The cable laid with so much difficulty across the Persian Gulf—the link which is, to borrow an architectural phrase, the key-stone of the arch of the whole undertaking—has, like its great Atlantic prototype, been broken. This is a fact as frequently asserted, and as often denied, in the fluctuating telegraphic news of our Western contemporaries. But we are glad now to be able to state authoritatively that the rupture luckily took place in shallow water; that all conceivable efforts of modern science and energy are applied to effect its comparatively easy repair; and that Colonel Stewart, and the other promoters of the enterprise, now in Constantinople, are in hourly expectation of receiving news by way of Egypt that the repairs have been effected, and that communication is restored.

That being the case, in what way will the line be completed to Western Europe? The Turkish line—the line from Bagdad through Turkish territory—hangs fire. Passing through a chronically-disturbed district, the district occupied by the nomad tribes of the Montefiks—tribes which still keep up in the heart of Asia Minor the picturesque traditions of the independent and semi-robber clans of old—the physical construction of the line meets with easily conceivable impediments. The Turkish pashalic Government, being scarcely able to maintain its authority and hold its own in this seething territory, is hardly in a position to afford much real help and protection to the common-place but essential requirements of theodolite carriers, surveyors, pole erectors, and the rest of the requisite mechanical constructors of a telegraphic line. Irrespective, however, of Arab disturbances, a deadly enemy stops the way of the material march. At this season of the year the mephitic exhalations from the Tigris, and the swampy lands which border it, are perdition to all within their reach, and furnish an invincible practical obstacle in the way of labour. It is not to be hoped that the line in this direction can be continued in the present year. But fortunately another route is open, not through Turkish territory, but by way of Persia—a circuitous route certainly, but a route which, presenting no physical obstacles whatever, and being prolific only in diplomatic difficulties, has been thoroughly utilised by the skill and energy of English engineers. This long portion of the Anglo-Indian telegraph is now complete, with the exception of what the Scotch would call a "bittock" at the Turco-Persian frontier. This brief lapse could be completed in a few days, and news brought direct to Constantinople from Bombay. Telegrams might now be received in ten minutes from Bushire. Unhappily, however, a political difficulty here intervenes. The Persian and Turkish Governments cannot agree on the frontier question. It is only plain justice to state that the fault does not lie with the Turkish Government—they are ready to facilitate the enterprise in every way; but the obstacles have cropped up out of Persian perversity. Why do the Persians raise difficulties? Not in any way wishing to foster Mr. Urquhart's Russophobia, we owe it to truth, nevertheless, and to the sequent facts of history, to state that the Persian Government has been prompted in this course of obstructive obstinacy by the direct agency of the Russian Government, who jealously dislike any disturbance of their universal monopoly in Persia, and who, having a telegraphic line of their own in course of construction through Persian territory, do not hesitate to throw all obstacles in the way of the completion of the great Anglo-Indian line of telegraph through the Persian dominions. This is, however, a matter rather for diplomatists, and we do not doubt that the difficulties of the nature referred to will be, with time, patience, and remonstrance, duly overcome.

Thus we shall get this great line linked with Constantinople, and telegraphic messages from Cornhill to Calcutta will pour to and fro. In its affiliation in this way with the Turkish line of telegraphs, the hearty co-operation of the Turkish telegraphic authorities is of essential importance. This has all along been understood; for many months past *pourparlers* on this subject between the representatives of the Anglo-Indian line here, telegraphic and functionaries, the English embassy, with all its power and authority, in a quiet way have been the order of the day. And we are glad to learn that the new Director-General of Turkish telegraphs, Agathon Effendi, clearly discerns the great international importance of this matter. He manifests a sincere desire to co-operate and aid. He wishes to identify the Turkish telegraphic administration with this vast enterprise, and concurs in the arrangement that English clerks, who are best suited to expedite English messages, should be appointed throughout the whole transit in Turkey, and that these clerkships should be bestowed, not on account of any personal favouritism, but in consequence of legitimate qualification alone. This is the exact story of the present position of the Anglo-Indian telegraph. It would require a pamphlet to enter into all the details, and dilate upon the manifold considerations which the work suggests; but he who runs may read what we have written, and gather an accurate notion of the position of the enterprise at this moment.

The actual position of the Indo-European line of telegraph—instantaneous connecting link between India and home—is of so much interest and importance, that every detail of its progress will be watched with eager interest. Having already described what in the main are the political and international circumstances of the undertaking, we will give a rapid summary and synopsis of the existing material conditions and general prospects of this great telegraphic enterprise. The subject might make an abstruse German philosopher reflect, and at the same time stir the flagging pulses of the most torpid Turk. The Atlantic telegraph between both hemispheres, spanning the ocean and bringing England and America into immediate contact, has been the first to pioneer the way. Its practicability has been indubitably established through the messages between the American President and our Queen, which were flashed along the electric wire across the broad Atlantic; and the Great Eastern—that mammoth vessel whose career is in itself a sort of unhappy romance—is now making ready to convey a new and improved cable for submersion in the deep, in order to accomplish the scientific and civilising mission to which it is destined.

While we look with interest at the effort to connect England with America by the agency of the submarine wire, we look with even nearer and keener anxiety to the great telegraphic enterprise which will bind India and Europe together, and make the two worlds one. A single fact is worth a flood of general speculations; and we cannot better give a clear idea of the actual condition and hopeful prospects of the Indo-European telegraph than by a short report of the interchange of messages which took place by that line on the 17th and 23rd instants between Constantinople and Bagdad.

Communication was commenced from Constantinople, from the Turkish telegraph-station at Scutari, on the Asiatic side of the Bosphorus. There were in attendance here—Agathon Effendi, the new Director-General of Turkish telegraphs; Lieut.-Colonel Stewart, R.E., C.B., Director-General of the Government telegraph to India; Mr. L. W. Courtenay, the resident delegate of the Indian Government in Constantinople for the enterprise; as also Mr. A. Kersting, assistant-superintendent, and Colonel Goldsmid, who had just returned from an inspection of the whole line from Bagdad. At Bagdad, Lieut.-Colonel Kemball, C.B., Her Majesty's Consul-General, with some Turkish authorities, and the local telegraphic staff, were in attendance. The communication was most satisfactory. The average speed sustained was from eight to ten words a minute, and there is no doubt that when all the intermediate stations are thoroughly acquainted with the relays, and acquire that facility in their work which practice alone can give, this speed will be exceeded. Conversation was kept up briskly throughout Asia Minor, to and from the Sea of Marmora and the Persian frontier. The distance from Constantinople to Bagdad is about 1,330 miles, the line passing throughout through Ottoman territory: and the intermediate stations, with the intervening distances, are as follows:—Scutari to Ismid, 55 miles; Ismid to Mudurlu, 104 miles; Mudurlu to Angora, 111 miles; thence to Yuzgat, 113 miles; thence to Sivas, 140 miles; Kharpoot, 178 miles; Diarbekir, 77 miles; Mardeen, 61 miles; Djezireh, 104 miles; Mossul, 91 miles; Kerkook, 114 miles; Bagdad, 189 miles. Of these stations the principal are (in addition, of course, to Scutari and Bagdad), Angora, Yuzgat, Sivas, Kharpoot, Diarbekir, Mardeen, and Mossul. From Bagdad to Fao, at the mouth of the Shat-el-Arab on the Persian Gulf, through which the line will pass when the Montefik Arabs and the healthy season will permit its safe construction, is 400 miles. From Fao to Kurrachee the submarine cable stretches along the bottom of the Persian Gulf for 1,300 miles, and 500 miles further carry us across a portion of our Indian empire to Bombay. "What do you wish to know?" asked Colonel Kemball at Bagdad of Colonel Stewart at Constantinople, when the telegraphic communication was made. "Have you any news of the Persian line, and of the repair of the cable?" was Colonel Stewart's inquiry. Colonel Kemball, in reply to this and succeeding questions, answered that the Amberwitch was busy repairing the cable, and that news of its completion might be daily expected; that the health of the telegraphic staff at Fao and Cape Mussendom was quite satisfactory, but "very unhealthy," unfortunately, at Bushire. Colonel Kemball also undertook, at a suggestion of Colonel Stewart, to write by

the Persian courier, who was just then about to leave Bagdad for Teheran, to Colonel Champain, who has charge of the construction of the Turco-Persian line, requesting him to telegraph to London the news of the completion of the repairs of the cable as soon as effected, and the probable period of the opening of the Turco-Persian line. Colonel Kemball then asked what was the latest news from America, and it was replied that General M'Clellan had been nominated candidate of the Democratic party at the Chicago Convention, and there might be some probability of peace. Colonel Kemball then telegraphed that he, and the other subscribers to the *Levant Herald* at Bagdad, received their papers very irregularly, which was a great deprivation to them, and begged of Colonel Stewart to apprise the editor of the circumstance. [The gallant colonel's message has been duly communicated to us, and we have made it the subject of formal complaint to Agiah Effendi, the Postmaster-General. We regret to state that the Turkish post is vexatiously irregular.] A lengthened conversation then ensued as to measures to be taken for the completion of the line to Bussorah as soon as the state of the country would allow it; details were entered into with respect to the distribution of stores, materials, &c., and the *séance* closed with mutual thanks and congratulations.

All interested were much gratified at this successful practical experience of the direct working of the Indo-European line, and we are sure that our readers, both here and at home, will cordially share their satisfaction. Agathon Effendi was much pleased; and we are glad to know that the new Director-General of the Turkish telegraphic service fully appreciates the importance of this line to the Turkish empire, and the great increase of Turkish telegraphic revenue which must accrue from its working. Colonel Stewart and his colleagues are preparing the tariff of charges to be adopted; and we may mention for general information that the cost of a message of twenty words from London to Calcutta will be fixed at about £5, and so on in proportion.

ON THE INFLUENCE OF TEMPERATURE ON THE ELECTRIC CONDUCTING-POWER OF ALLOYS.*

By Augustus Matthiessen, F.R.S., Lecturer on Chemistry in St. Mary's Hospital, and Carl Vogt, Ph.D.

The influence of temperature on the electric conducting-power of the pure metals in a solid state has been proved to be very great,† and as very little is as yet known with regard to the influence of temperature on the electric conducting-power of alloys, we undertook this research in order, if possible, to discover the law which regulates this property.

For the sake of clearness, we have thought it advisable to divide this subject into four parts, and they will be treated of in the following order:—

1. Experiments on the influence of temperature on the electric conducting-power of alloys composed of two metals.
2. Experiments on the influence of temperature on the electric conducting-power of some alloys composed of three metals.
3. On a method by which the conducting-power of a pure metal may be deduced from that of the impure one.
4. Miscellaneous and general remarks.

1. *Experiments on the Influence of Temperature on the Electric Conducting-power of Alloys composed of two Metals.*

It will be as well to mention that, from the few experiments already published on the influence of temperature on the conducting-power of alloys, we had at the commencement of the research some idea of the law which regulates this property, and having found after a few experiments our supposition confirmed, we were able to shape the course we intended to pursue in such a manner as to curtail the number of alloys to be experimented with. Thus, with the alloys made of the metals, lead, tin, cadmium, and zinc, with one another, instead of using the alloys

$$Pb_6\,Sn,\ Pb_4\,Sn,\ Pb_2\,Sn,\ Pb\,Sn,\ Pb\,Sn_2,\ Pb\,Sn_4,\ Pb\,Sn_6,$$

and testing in the same manner the tin-cadmium, tin-zinc, cadmium-zinc alloys, we only used the following,

$$Sn_6\,Pb,\ Sn_4\,Cd,\ Sn_2\,Zn,\ Pb\,Sn,\ Zn\,Cd_2,\ Sn\,Cd_4,\ Cd\,Pb_6,$$

thus forming a mixed but complete series. Other groups of alloys have been treated in a similar manner. The reason for grouping alloys made of different metals under different heads has already been elsewhere discussed.* It has also been only considered necessary to experiment on one wire of each alloy, as the results obtained agree in most cases very closely with those calculated, and as it has been proved by a few determinations, which are given in the following table, that the same values were obtained for the percentage decrement in the conducting-power of the alloy between 0° and 100°, when series of determinations were made with two wires of the same alloy:—

Alloy.	Volumes per cent.	Percentage decrement observed between 0° and 100°.	Remarks.
Gold-copper (hard drawn)	98·63 of Au	21·87	Series made with wires of different specimens of the alloy.
Gold-copper (hard drawn)	98·38 "	21·75	
Gold-silver† (hard drawn)	52·08 "	6·50	
Gold-silver (hard drawn) .	52·08 "	6·48	
Gold-silver (annealed) . .	52·08 "	6·72	
Gold-silver (annealed) . .	52·08 "	6·70	Two series of determinations made with the same wire.
Gold-silver (annealed) . .	52·08 "	6·71	
Gold-silver (annealed) . .	79·86 "	10·15	
Gold-silver (annealed) . .	79·86 "	10·21	
Tin-cadmium	23·50 of Sn	28·89	Series made with different wires of the same specimen of the alloy.
Tin-cadmium	23·50 "	29·08	

The method and apparatus employed for the determination of the conducting-power at different temperatures was the same as that described and used for the experiments on the pure metals.‡ We have, however, in many cases only taken observations at three intervals, as we found that almost the same formula was deduced from observations made at three different temperatures as from seven, especially when the temperature of the second observation was the mean of the other two; now, as three or more observations were made at each interval, it was easy to obtain the wished-for temperature as the mean of several determinations. Thus, the formulæ deduced for correction of conducting-power for temperature of the alloy $Cd\,Pb_6$ were—

From seven observations . . . . . $\lambda = 9{\cdot}287 - 0{\cdot}032501t + 0{\cdot}00006743t^2$.
From three observations . . . . . $\lambda = 9{\cdot}286 - 0{\cdot}032450t + 0{\cdot}00006683t^2$.

Again, those deduced for the alloy $Sn_2\,Zn$ were—

From seven observations . . . . . $\lambda = 16{\cdot}876 - 0{\cdot}065544t + 0{\cdot}0001471t^2$,
From three observations . . . . . $\lambda = 16{\cdot}899 - 0{\cdot}065790t + 0{\cdot}0001454t^2$,

where λ represents the conducting-power at $t°$ C.

We have here taken, as in former papers, the conducting-power of a hard-drawn silver wire at 0° = 100 as defining our unit. The normal wires were made of German silver, the resistances of which were determined by comparing them with the gold-silver alloy,* the conducting-power of a hard-drawn wire of which is equal to 15·03 at 0°.

The tabular statement hereunder contains the conducting-powers, specific gravities, and equivalents of the metals used for making the alloys. These values are those which have been used in calculating the results given in this paper:—

Metal.	Conducting-power at 0°.	Specific gravity.	Equivalent.
Silver (hard drawn)	100·00	10·468	108·0
Silver (annealed)	108·57	—	—
Copper (hard drawn)	99·95	8·950	31·7
Gold (hard drawn)	77·96	19·265	197·0
Gold (annealed)	79·33	—	—
Zinc	29·02	7·148	32·6
Cadmium	23·72	8·655	56·0
Palladium (hard drawn)	18·45	11·500	—
Platinum (hard drawn)	17·99	21·400	—
Iron (hard drawn)	16·81	7·790	—
Nickel	13·11	8·50	—
Tin	12·36	7·294	58·0
Thallium	9·16	11·900	—
Lead	8·32	11·376	103·7
Bismuth	1·245	9·822	208·0

In the treatise before us the authors here append a number of tables, which would occupy too much space if reproduced in these columns, showing the results obtained with the alloys belonging to

different groups, with some alloys made of those metals which, when alloyed with one another, conduct electricity in the ratio of their relative volumes; and those with some alloys of those metals which, when alloyed with one another, do not conduct electricity in the ratio of their relative volumes, but always in a lower degree than the mean of their volumes, &c.

(To be continued.)

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.*

A.D. 1766, June 10.—No. 850.—Knight, Gowin [Gowan].—"Constructing compasses, so as to prevent them being affected by the motion of the ship," &c. "The card and box" "are made to oscillate in equal times, by placing the centre of gravity both of the box and of the card" at proper distances "from their points of suspension," and by fixing an adjustable weight to act as a "pendulum" "to the rim of the outward gimbol, under the axis, by which the outward gimbol may be made to move in the same time as the inward. The inward axis or gimbol is fixed to the bottom of the box." The agate receives the point on which the needle moves, that point being attached to the needle by means of a metal "cross piece," having "small gimbols." "The agate is fixed to a slender stem of metal, the lower end of which is pointed," and turns freely in "a hollow socket." "The socket is fixed as a pedestal in the centre of the bottom of the box, and has a slit on one side," to admit a pendulum screwed to the lower part of the stem. When "the box is in motion," the pendulum, "stem, and agate, will move to and fro." Also, "constructing the variation compass," "for taking the sun's azimuth and amplitude, and the bearing of distant objects." A moveable "mirror is placed at each end of the index, just behind the sights," "so as to reflect" "the graduated rim of the card, which will then appear to the eye" vertical, and cut by the "thread of the opposite sight," which also cuts the object. "In taking the sun's azimuth," when its height is considerable, "the rays of the sun are reflected from a small polished cylinder placed behind the sights, and an opening is made in each end of the index bar, that the brass rim may be reflected without interruption from the bar, which is slit, that the shadow of a thread underneath it may cut the graduated rim of the card."

A.D. 1779, June 25.—No. 1229.—Wright, Gabriel, "a new-constructed and amplitude compass." "The new-invented parts" and "improvements" consist of:—"A horizontal nonius (or verniers) division," "having a vertical motion" by means of a nut outside the compass box. An "index and sights, which goes on the compass box," used when the sun's azimuth or amplitude is taken. Two "mirrours" are "placed at right angles to each other on the plane of the index;" also "a screen or dyed glass," and "a convex glass." "To the vertical sight" "is fixed a horizontal one," "to look down on the reflecting glasses, &c., to view the sun and the horizon of the sea, and to read off the degrees from the card, &c., through the convex glass." "At the other end of the index" is placed a weight "to balance the whole." Also an improved "reflecting quadrant or octant, having the following new parts:"—"A round plate" (with "a hole," "a circular slit," and "a milled edge"), "carrying the index glass," and moving round the centre of the index, adjusted by a "clamp and screw;" "a horizontal screw" adjusts the index glass to the horizontal glass. The index glass has a horizontal fine hair line. A piece of brass is screwed to the quadrant frame, having "a fine division cut on it," and adjusted "to coinside with a like division cut on the edge of the round plate." A "sight vane," "having a piece of thin brass with a hole in the centre," sliding up and down in a "slit," "so as to view objects in the true plane of the quadrant." "A brass frame," carrying a hair line, which sometimes takes the place of the sight vane. A "sight vane," with two lines drawn across the inside ("used with the compass in taking the sun's azimuth and altitude at the same time"), is "fastened to the arch of the quadrant." "A reflecting glass," to view objects from 140 to 180 degrees apart. "A cylindric box with two parallel glass sides," filled with a liquid that will float a hair (attached to a cork and weight) vertically, "to level the compass by when the horizon of the sea cannot be observed."

* Published by authority of Her Majesty's Commissioners of Patents.

A.D. 1782, February 5.—No. 1318.—Nairne, Edward.—This invention is stated in the title to be a "New-invented and most usefull improvement in the common electrical machine (which I call the insulated medical electrical machine), by insulating the whole in a particular manner, and constructing the conductors so that either shocks or sparks may be received from them." The "form to be excited" of this electrical machine is "supported immediately on non-conducting substances." "The conductor or conductors which either give to or receive the electrical fire from the excited part, is composed of a coated electrical jar or jars, or any other substance than" [that?] "can receive a charge of electricity or conducting substance connected with them." Connected with these "conductors" are "tubes" or "rods," with ball and socket joint or joints, that will conduct electricity, to direct the electric discharge to any part of the body required; and by these means shocks are given by discharging the electricity (either by metallic connection with the earth, or with the conductor of the opposite kind of electricity) when at some distance from the part through which the shock is to be sent; if sparks are required the distance is lessened. By means of the "conductors" and jointed "tubes," the human body can be in any part affected with either kind of electricity in any convenient manner.

A.D. 1782, March 20.—No. 1322.—Heriot, James.—A "New invented mariner's compass, with compass boxes or bittacles, pendent or standing, with ventilator, to contain either lamp or candle, as occasion may require, calculated to obviate every difficulty which those of late use have been subject to, for the purpose of navigating all kinds of ships or vessels."

A.D. 1788, August 12.—No. 1663.—McCulloch, Kenneth.—"A mariner's compass on a new construction." An "azimuth compass" is described and shown, in which gimbals are dispensed with. The "compass vessell" is supported on a pivot at its centre of gravity, which is brought as near as possible to that of the needle; the needle moves upon a point "a small distance above the centre of gravity," and near to ~~the centre of motion~~ on which the compass vessel is free to move. For this purpose the bottom of the compass vessel "rises in a conical form," is supported upon a "prop," free to turn in the outer case of the instrument, and has a "ring of lead" round its bottom "to balance" it; two arms, with slits, in which "pivets" are free to traverse up and down, spring from the prop and turn with it when necessary; the pivots are fixed to the compass vessel "in a line with the thin metal plate on which the pivot of the needle rests." The needle is "bent so that the point of the pivot" "is a small distance above the centre of gravity." Besides the above, the compass is fitted with an azimuth circle round the edge of the card, a nonius stop with a slide passing through one of the pivots, a metal bar carrying a magnifying glass to read the divisions of the azimuth circle, and "sight vaines." A "steering compass," on the same principle as the azimuth compass, is described and shown, having the arms with slits, and the prop screwed into the outer case. Another compass is described and shown. The compass vessel is supported by "jimbals," and the inverted cone in which the needle pivot rests has a weight attached to it mounted in small "jambols." The smaller jambols are supported by standards rising from the bottom of the compass vessel. In this compass all the centres of motion are as nearly as possible in "the same horizontal plain."

A.D. 1791, July 5.—No. 1815.—Wright, Gabriel.—A new method of making mariners' compasses. A "gimbel compass" is described and shown, in which the "inside compass box or kettle," made of wood, or any metal except iron, has "a ring of lead" fastened "on the outside and near the centre of motion, "to balance" it. "A metal pedestal" is fixed on the centre of the bottom of the compass box, to which various "pillars or points" "are screwed on and off at pleasure, being all at different times made use of to carry or suspend the magnetic needle and cards. A "hollow metal cone," with a point at the top to receive the needle, is generally placed on the pillar or point screwed into the pedestal; the needle may, however, be placed on the pillar without the hollow cone. Three different "pillars or centres" are described and shown; one with a point to receive the needle; another "with a round top" to receive the hollow cone; and a third with an "agat cap" and gimbals. The needle may either be mounted with a reversible "agat cap," which is kept in its place in a "cylindric brass box" by a helical spring, or it may have an adjustable inverted steel point mounted with a helical spring in a brass box; this last is used with the "gimbel centre." The above compass, cards, and needle, are used in the azimuth, amplitude, steering, and hanging compasses; also in "the conical compass with the new invented semicircle to

prevent its turning round horizontally on its centre or prop." The azimuth compass has the following observable points:—On its card are drawn "a number of lines" "parallel to those usually drawn through the centre," "quite across from the divisions on one side to those opposite." A metal circle, semicircle, or quadrant, having a jointed index moving from the centre, with a vernier; this "may either be made fast to the brass ring or cover of the compass, or made use of detached, having a handle to fasten to it for the last-mentioned purpose." "One or two sight vanes." "On the plane of the circle, semicircle, or quadrant, is placed one or two metal frames, which contain reflecting plain mirrors," "to show the horizon of the line by which means the compass is kept in a horizontal position by the marine horizon."

A.D. 1792, June 19.—No. 1891.—Fullarton, William.—"Certain new methods of separating iron from iron stones and other ores of that metal, of smelting it into the state of pig or cast iron, and of reducing or refining it into the state of malleable or forged iron." The ores are first to be "reduced into a pulverized state," "previously calcining the material when necessary," "and passing the same through sieves or bolters." Then the extraneous matters are separated "by all or any of the following operations (namely,) by washing, levigating, triturating, wennowing, *and by the application of magnetic attraction*, according to the nature and qualities of the different stones and ores." The materials thus purified are to be put into a furnace. A furnace, "to act as a crucible," is described, also the method of using it in this invention, for which it is used in preference to any other kind of furnace.

A.D. 1794, March 18.—No. 1980.—Nugent, Patrick Rooney.—"Two instruments whereby the latitude, longitude and magnetic variation at sea or on shore may be obtained." "An universal reflecting sextant, oxtant, or quadrant," "a glass tubb and bubble," and "a pendulum for taking altitudes without an horizon," are described, and their use elucidated. "A steering or universal azimuth compass" is described, with "an aperture of 45° horizontal width," "cut out of the side of the kettle," half on each side of its shoulders or axis. "Immediately above them" are "two plain sights," firmly fixed so that their central hairs are "exactly opposite to the north and south points "of the card or needle." The apertures "are to be glazed with glass or ising-glass." A method of finding the magnetic variation by this compass is given.

A.D. 1796; January 19.—No. 2081.—Wright, Gabriel.—An azimuth and amplitude compass is described and shown, in which the following additions are made, "by which any one person, without assistance, is enabled to take the azimuth of all celestial objects and their altitudes at the same time, and in every latitude or altitude of the object." A "reflecting octant" fastened on to the top rim of the compass, "in a vertical position," by screws. A "reflecting speculum," and adjustable convex lens, mounted in a sliding tube, used to reflect and magnify the divisions on the card and nonius "in a horizontal view, to be read off by the observer at the time of observation without any personal assistance." A "jointed sight vane with a silk line" to "observe by the sun's shaddow;" also a sight vane with dark glass for taking the azimuth. A method of stopping the compass card by the action of two parallel "bent levers or bridles," one end of which "screws on to the nonius piece," and the other on to an open stop piece on the opposite side of the card; thus, by pressing a nut connected with the nonius piece, the levers cause the card to be pressed in two opposite directions, and stop it without error. An "artificial horizon" to be used with the octant, a "dial and index" "to shew the ship's run during the interval of time in making two observations of the sun's azimuth and altitude," a "screw," with an "index" and "scale" used with the dial, and a scale and quadrant made use of for solving nautical problems, are also described and shown.

A.D. 1798, March 10.—No. 2221.—Perkins, Benjamin Douglas.—The title of this invention is as follows:—"Discovery of a certain art of relieving and curing a variety of aches, pains, and diseases in the human body, by drawing over the parts affected, or those contiguous thereto, in certain directions, various pointed metals, which, from the affinity they have with the offending matter, or from some other cause, extract or draw out the same, and thus cure the patient." The invention consists in employing those metals "which produce that action on the nerves and muscles of animals known by the term galvanism." "Combinations of copper, zink, and a small proportion of gold, and also iron united to a very small proportion of silver or platina," are found most efficacious. Instruments are made with points, which are applied "to those parts of the body which are affected with disease," and drawn "off on the skin to a considerable distance from the complaint, and usually towards the extremities." "The diseases most readily cured by this metallic influence are rheumatism, gout, pleurisy, inflammation, spasmodic affections, and most kinds of topical complaints. All parts of the body on which the metals are to be used, as well as the metals themselves, should be perfectly free from oily and greasy applications. The relief from this metallic application" takes place in from fifteen minutes to "several weeks," according to the nature of the disease.

A.D. 1798, June 27.—No. 2246.—Nugent, Patrick Rooney.—"New invented and improved mathematical instruments, whereby the latitude and longitude, variation and inclination of the magnetic needle at sea and on shore, may be obtained in a more general, masterly, and perfect manner than hath hitherto been done."

A.D. 1798, December 17.—No. 2280.—Peckham, John Randall.—"A new and improved method of constructing a watch so as to unite it with a mariner's compass, in such a manner as to answer every purpose with equal accuracy and perfection for which either of them might be separately used." "My method of constructing a watch so as to admit the uniting it with a mariner's compass, in such manner that the works of the watch shall not affect the magnetic needle nor be affected by it, is this:—I substitute for those works which are usually made of steel, and which are near enough to affect in the smallest degree the free action of the magnetic needle, works made of gold, silver, or any other metal or admixture of metals which have no influence on the magnetic needle, (that is to say) in all cases (whether the mariner's compass be inserted in or upon the face of the dial in any part, or in any part of the back of the watch, either in the box or case), for the following parts usually made of steel (viz.), the barrel, arbor, cannon, pinions, ratchets, and clicks, bolt, bolt spring, detant work, stopworks, cap, spring, and screws, and for every article or part where steel is not absolutely required, I substitute gold, silver, or some other metals or admixture of metals, as above-mentioned."

A.D. 1805, October 7.—No 2883.—Syeds, John.—"An improved steering amplitude or azimuth compass." A compass is described and shown, in which "the outside gimboal" is taken away, and the kettle is suspended on pivots in the "betical" [binnacle?], with or without a wood box; the pivots on which the kettle is suspended prevent the pitching of the ship from affecting the needle. To prevent the needle from being affected by the rolling of the vessel, "a half gimbol," to which the needle centre is fixed, is suspended inside the kettle on pivots at right angles to those suspending the kettle, thus giving four suspending points to prevent the card from being disturbed by the motion of the ship. In this compass the "lubbard's point" [lubber's line?] is marked on the half gimbal, and is therefore not obscured by a side light when the ship is rolling. The amplitude compass is the same as the steering compass, except that it has pins to receive sight vanes, and a deeper cover. An azimuth compass is also described, in which there is "a spring to the nonius and a trigger," to which is fixed a thread for the observer to stop the compass card by; there is a drawing evidently showing this, but not referred to in the specification. To keep the azimuth compass from wear, when not in use, there is "a notch in the standards to place the suspending pivot into when wanted for use, and to take it therefrom and place the compass in the bottom of the box when not wanted to be used." A "scale," to work various nautical problems connected with the ship's course, is also described and shown in detail.

A.D. 1809, September 26.—No. 3265.—Smith, Egerton, and Harris, Michael.—"Certain improvements in ships' binacles and compasses, and in the mode of lighting the same." This invention, called "The patent tell-tale binacle and compass," consists in the following improvements:—1st. The compass is visible on deck and in the cabin "at the same time." 2nd. The compass is illuminated by the same light which lights the cabin. 3rd. Preventing the compass card from being unshipped. 4th. "In enabling the mariner to steer with one compass only," and a small binnacle. 5th. In "darkening the binacle," so "that whilst the compass is distinctly visible," "no light shews" "to an enemy." These improvements are effected as follows:—"The compass bowl is open at the top and bottom. The compass card is of "paper, parchment, silk, cloth, with or without talk" [talc?], "glass, or other proper substance, printed on both sides;" or "a card of metal, with either the points or the interstices cut out, and the spaces filled up with paper, printed or plain, pasted over its whole surface," may be used. "Two card faces" may be pasted together, "with their faces outwards," or an impression may be taken from the engraving, having a sheet of transfer paper on the side of the card

not printed on by the block. To load the card, it is stretched upon two metal rims, rivetted, one on the upper, the other on the under surface. The card centre is supported either on a bar fixed across the bottom of the compass bowl, or fixed into a hole in the lower glass by a screw and nut. Another bar, with a wire projecting into the hollow top of the needle cap, is fixed across the top of the compass bowl, which prevents the card being unshipped. The light is admitted from the cabin by openings in the deck, binnacle, and compass box. A "slide" is placed in the binnacle, "just above the compass box," to exclude unnecessary light. The invention is applied to compasses of the usual construction, by reflecting the light from below to the face of the compass by a mirror.

CORRESPONDENCE.

MR. BRITTAN'S PLAN OF COMMUNICATION BETWEEN GUARDS AND ENGINE DRIVERS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I am not in possession of the date when Mr. Brittan published his plan for effecting communication between the guard of a railway train and its engine-driver, but I find a plan suggested in the pages of the Mechanics' Magazine for September, 1847, which appears to me to embrace that proposed by Mr. Brittan.—Yours, &c., TYRO.

"Let there be fixed upon the roof of every carriage a small staff, moving on a fulcrum, with a flag attached to the long arm thereof; and from the short arm let a wire or rope be carried into every compartment of the carriage, to act as a bell-rope; so that, in case of accident or illness, the passengers, by pulling in the rope, could raise the flag-staff perpendicularly from its horizontal position, thereby giving a signal of danger to the guards. For night signals, the ordinary lamp of the carriage would be substituted for the flag. And for effecting a communication between the guards and the engine driver, I would suggest the following simple and inexpensive means:—Let a small lead, tin, or copper tube be laid the whole length of every carriage; and for connecting the tubes between the carriages, so as to form a continuous tube the whole length of the train, I would have a piece of India-rubber tubing inlaid with a spiral spring. One end of the long tube would be fixed to the steam pipe, so that a jet of steam could be made to traverse the whole length thereof, and escape at the distant end. At the seat of every guard a stop-cock would be fixed in the tube, so that he could, on perceiving a signal of danger, stop the current of steam, which would then ascend a branch pipe furnished with a whistle, near the engine driver, and cause the same to sound, or remove a detent from a bell machinery. This tube would, in the case of a carriage running off the rails, or becoming detached, be self-acting; for the elongation and consequent collapsing of the India-rubber and the spiral spring, would stop the current as effectually as the "*stop-cock*," and cause the same result. Arrangements in connection with the engine could be made to cause a current of air to traverse the tube in substitution for steam, if it were more desirable—the intersecting tubes of India-rubber, &c., could be instantly attached and detached by the adoption of slides, &c.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I do not agree with your correspondent, R. S. Culley, that the plan of signalling proposed by Mr. Brittan, by having a whistle on the roof of the guards' van, worked by compressed air, would in the least *weaken the significance* of the engine whistle. The sound emitted by the guards' whistle would be quite different to that of the engine. As a practical engineer, I think that Mr. Brittan's plan is a very good one, and could be relied upon. It is very desirable that some such plan should be adopted, as there can be no question but that many serious accidents would be averted, thereby increasing the public confidence in railway travelling, which has of late been seriously affected. There have been, within the last few weeks, about twenty patents taken out for improved means of effecting the object in question; of their merits I cannot speak, as they have not yet been specified. However, my opinion is that no arrangement will be adopted until a director, a bishop, or a prime minister, as predicted by the late Sydney Smith, is sacrificed in consequence of the absence of the means of communicating the existence of danger. In the papers of this day an account is given of one of the carriages in a train having taken fire, to the great terror and danger of its occupiers, who possessed no means of averting the progress of the train. Yours obediently, A DRIVER.

13th October.

THE NEW ATLANTIC CABLE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—It appears to me somewhat strange that the Directors of the Atlantic Telegraph Company should involve the shareholders in a second expense of testing specimens of cables after what had been done under the direction of the Telegraph Committee of the Board of Trade, of which the company's chairman, engineer, electrician, and secretary were members. Several lengths of a cable, constructed upon the same principle as the one now adopted, and manufactured by the same parties, was considered the worst adapted rope for deep-sea purposes of all those subjected to experimental test, from its liability to kink, and its enormous elongation when weighted, and the return or contractibility on the removal of the weight forcing the core out clean between the strands, as appears from a sketch in the Committee's Report. Yet Mr. Fairbairn, who was a member of that committee, and whose signature is appended to the report, has actually recommended the adoption of such a cable, although when challenged by Captain Selwyn as to the correctness of its mechanical construction, at the late meeting of the British Association at Bath, Mr. Fairbairn admitted the soundness of the gallant Captain's objections. Captain Selwyn objected to "a spiral covering combined with a straight internal wire, as incompatible with security from disruption," and Mr. Hawkshaw an engineer of great experience, said at the same meeting "no one would dispute that Captain Selwyn was right in principle." PROGRESS.

[The subject towards which our correspondent calls attention is certainly one of great importance. The selection of a cable constructed upon principles which have in every instance failed in practice is inexplicable to us.—ED. *T. J.*]

TELEGRAPHIC NEWS.

WEST HAM GUTTA-PERCHA COMPANY.—This company's premises being required for metropolitan improvements, arrangements have been effected whereby its interests will be united to those of "the India-rubber, Gutta-percha, and Telegraph Works Company, Limited."

THE ELECTRIC TELEGRAPH IN INDIA.—The Indian telegraphic lines are being rapidly extended, but great complaint is heard of the delay in the transmission of messages. The Indian Government is urged to surrender the management of these lines to some public company. The Oriental Telegraph Company has made an offer to work them.

IRREGULARITIES ON THE INDIAN TELEGRAPH LINES.—By advices per the last mail from Bombay, we learn that "a commission is to be appointed to investigate the causes and origin of the great irregularities in the working of telegraphic communication throughout India, and to examine into the efficiency of all the officers and employés connected with the department."

TELEGRAPHY ON THE CONTINENT.—Tourists will be glad to learn that the Brocken, the highest mountain of the Hartz Mountains, will be, by next spring, connected with Ilsenburg, thus enabling them [tourists] to ascertain the state of the weather, the friends they are likely to meet there, and the nature of the accommodation they can expect.

SHOCK OF EARTHQUAKE AT GWADUR.—A smart shock of earthquake was felt at Gwadur, on the Mekran coast, on the 25th August, but it did not do any serious mischief. The wave passed from north to south. Portions of the ledges of the Mekran and Gwadur mountains were thrown down with a tremendous crash.

THE ELECTRIC AND INTERNATIONAL TELEGRAPH COMPANY.—At a meeting of the General Purposes Committee of the City of London, Mr. Cromwell Varley, electrician to the Company, applied for permission to be allowed to lay down a pneumatic tube of two inches diameter, for the transmission of telegrams, from the Company's office, in Telegraph-street, to the offices of the British and Irish Magnetic Telegraph Company in Threadneedle-street. The permission was immediately granted by the Court.

THE ORAN AND CARTHAGENA CABLE.—The *Sentinelle Toulonnaise* announces that "the submarine telegraph cable which was laid successfully between Oran and Carthagena, remained perfect only four hours, having become broken at a point supposed to be but a few miles distant from the Spanish coast. We are assured by several gentlemen well acquainted with the shores of the Mediterranean, that it will be impossible to manufacture a telegraphic cable sufficiently strong to resist the destructive influence of the reefs and submarine currents."

NEW GAS LIGHTING APPARATUS.—Mr. T. C. Ebdy and Mr. M. Burdon, of Durham, have brought out an apparatus for lighting gas, intended to obviate the necessity of its being done by hand. It is called the "electro-magnetic gas-lighting apparatus." The invention may be applied to any description of gas-lamp, without their requiring alteration. The apparatus is about three times the size of a lady's thimble, and very much like an ordinary gas-burner. The principles upon which it is based are stated as follows:—An ordinary telegraph wire, communicating with the negative pole of a galvanic battery, is connected with the electro-magnetic burners in succession, according to the number of lights required, and the extremity of the wire communicates with the earth, or is conducted back to the battery, and attached to the positive pole, when the circuit is complete. Therefore, to light and extinguish the lights, it is only requisite to connect or disconnect one of the poles of the battery. Immediately the current enters the electro-magnetic burner it passes through an insulated wire, which is wrapped round a soft iron tube, which immediately becomes a powerful magnet, and attracts a piece of soft iron, which opens a kind of valve and permits the gas to escape through the burner; at the same time the gas-valve is opened, the current passes through a piece of platinum wire close to the burner, which turns red hot and lights the gas. This effect is produced at every burner at the same instant.

Malta and Alexandria Cable.—The Fanny Lambert, screw steamer, returned to Malta on the 30th September, from her successful mission to repair the ruptured cable between Benghazi and Alexandria, some 140 miles from this latter port, which, after a lapse of twenty days, is again in working order. The defect did not, however, result to be where it was expected to be found, and where weakness is known to exist, so that it is more than likely we may have before long to deplore another like temporary interruption. The Fanny Lambert has been ashore on the Barbary coast, where some of the blades of her propeller got broken off, and she also sustained some trifling damage in her bottom, which luckily is a double one, for the repair of which damage, and in order to be fitted with a new propeller, she was taken into the government dock on the 1st of October.

The Indo-European Telegraph.—The *Scindian* learns that all messages between the home and Indian government will be transmitted in duplicate, one copy by the Persian Gulf, the other by Suez, as there are evidently good reasons for this precaution. The first, it secures messages against the muddle into which the process of transmitting them in Turkish, as stipulated by the Porte, must throw them; and, second, to avert total or complete miscarriage, in consequence of interruptions on the wire through Mesopotamia, or the cable down the Gulf. The line running through the Montific country, when completed, can scarcely be depended upon, owing to the relation existing between the tribes, very powerful and warlike ones, and the Pasha of Bagdad, against whom these people have risen in rebellion. This insurrection, which promises to be a protracted one, would not affect our position in these parts if we were permitted to use European and Arab workmen on the line, but the present Governor of Bagdad will consent to none but Turks being employed, and these the Arabs will assail whenever they can get a chance. The British government is also well aware of the frequency with which these difficulties between the Montific and Turkish authorities occur, that they were led, last October, to enter into treaty with others for the construction, by the latter power, of a line which shall effect a considerable detour, to avoid the disturbed district completely. This wire is to pass from Bushire, on the Persian Gulf, where the cable lands before starting 170 miles further, to its terminus at Shat-el-Arab, *viâ* Kazeeroor, Shiraz, Movighaut, Kormshah, Ispahan, Kashar, Korm, Teheran, Hamadan, Kermanshah, and Khanakeen, to Bagdad, the distance between Bushire and Khanakeen being about 1,100 miles. A glance at the map will show what a vast circuit has to be made to keep clear of the country which it takes only about 360 miles of wire to traverse. We are in hope to hear, however, that the work on the Persian line is being pushed on with so much energy that its completion is looked for shortly. We hope by the time this is done the cable beyond Gwadur will have been put to order. Should, however, submarine communication unfortunately turn out to be uncertain, it may become desirable to find a *route* for the wire from Shiraz to Gwadur. The country, we are aware is rather unsafe between these points, and much of it is a desert; but diplomacy must accomplish beneficial results with the tribes which dwell in it, whilst, no doubt, the impracticable spot could be avoided.

Military Balloon Signals.—The following communication appeared in the morning journals of the 10th instant. Electrical communications between the balloon and terra firma have frequently been successfully effected in the American armies. "The employment of telegraphic signals on the occasion of my recent ascent from the Crystal Palace has, I am glad to say, created some interest among military and scientific men. Just about ten years ago, when I suggested the use of reconnoitring balloons in the Crimea, I devised and experimented with a set of semaphore signals. I then ascertained that they could be easily worked, and that their action could be seen and understood by observers in possession of their meaning. From communications I have received since September 22, it appears that for ten miles in a south-west, south, and easterly direction, the signals, with the aid of glasses, could be distinctly seen; and, although on this afternoon they were merely set in motion without any definite meaning, still it is satisfactory to learn that ærial telegraphy can be made the medium of imparting valuable information either to the inhabitants of a large area or, if necessary, to the select few who may alone have the key to their import. For, example, if used for scientific purposes—say, as an ærial observatory to announce the time of day. This could be accomplished by the dropping of a huge black ball down a rope a few hundred feet long. By this means a numerous population could have a visible intimation of the exact hour, or of any other subjects of which simultaneous observations are desirable. But more especially, I believe, for military signals would the idea prove worthy of adoption. A balloon, just as I used mine for government experiments at Aldershot and the Arsenal, could be let up with ropes, kite-fashion, and the signals set in motion, either to direct the evolutions of an army, or to convey secret intelligence to the commander-in-chief. For reconnoitring during a battle there is no real necessity for risking the destruction of the balloon, as a mile or two from the car, at a very moderate elevation, appears almost close, and signal-arms of twenty feet in length, such as I use, can be discerned many miles away with the naked eye. It might prove of importance, in case of invasion, or the threat of it, to have the telescopic range of the southern and eastern portions of our island from stated heights up to several thousand feet; also to know from stations on our coast what amount of ocular acquaintance could be made with our neighbours' sea-board. This would be a good test for our most approved instruments, and would certainly aid military as well as scientific ballooning. —Henry Coxwell."

The British Association.—At the meeting of the above association at Bath, Admiral Sir E. Belcher read a communication from Captain Doty, of the Confederate States Navy, "On the Torpedoes used by the Confederate States in the Destruction of some of the Federal Ships of War, and the Mode of attaching them to the Rams." The torpedo consists of a shell filled with explosive material, whether gunpowder or gun-cotton, and is carried under the surface of the water at the end of a bar attached to the stern of the ram or other vessel, projecting some ten or twelve feet. The bar has a slight sliding motion, by means of which the end of the bar within the vessel, as soon as the torpedo strikes the enemy's ship, acts on a simple mechanical arrangement, bringing the wires connected with the torpedo into circuit with a galvanic battery, causing the explosion of the shell. Such an engine of war, Captain Doty states, having been attached to small wooden steamers, an attack was made by it against the Federal frigates, New Ironsides and Minnesota, and so much damaged them by the explosion as to render them unfit for further effective service, till docked for repairs. It was also employed in like manner against the new sloop-of-war, Housatonic, attached to the Federal blockading squadron off Charleston, which ship filled, and went down in eight minutes after the explosion of the torpedo under her counter. It is unhesitatingly asserted, by competent judges, that a vessel properly constructed for the use and application of the torpedo battery, and possessing superiority of speed, would prove a formidable antagonist against a number of frigates, armed with the heaviest metal, for it would, by advancing end on, present the least surface to their fire, and always under the most acute angles. An especial advantage which it possesses is, that it may be worked at all times; for instance, in a rough sea, when ordinary guns could not be used, while it may be employed with certain success, under cover of darkness, against an enemy's fleet, destroying, disabling, or driving them away from the coast altogether. Great economy, simplicity, and safety are, further, among the valuable and important qualities claimed for the submarine battery; neither the battery itself, nor the men working it, are in the least exposed, the apparatus being situated much below the line of flotation. Admiral Belcher proceeded to point out the superiority of such an engine of warfare over rams. A ram with a velocity of 10 knots overhauls and touches the stern of the vessel she chases, going at the rate of 9½ knots—a half-knot velocity would not injure her opponent, although it might impair her steerage, and bring her broadside to operate on her, in all probability, at such close quarters, to her detriment. But a ram fitted with the means of projecting a simple shell under the counter, or into contact with the screw, would inevitably destroy, or at least so derange rudder and screw that her great work of executing the ram manœuvre at right angles to her antagonist would no longer be matter of doubt; and surrender would, under such difficulty, doubtless result. The French and other foreign governments have approved of the plans of Capt. Doty. Our own Government ordered the examination of them by a scientific committee, and it has expressed approbation in an official communication.

Anglo-Indian Telegraph.—Sir Charles Bright writes the *Times* of the 9th instant as follows:—"It will interest those who have watched the progress of our telegraphic communication with the East to know that the injury to the telegraph cable, in the shallow water on the Mekran coast, lately reported in your Indian news, has been repaired. A telegram has been received by Sir Charles Wood, from Colonel Stewart at Constantinople, dated the 7th instant, conveying the substance of a message from Colonel Kemball, at Bagdad, of the 3rd instant, reporting the reinstatement of telegraphic communication between Bussorah and Kurrachee, and announcing the receipt at Bagdad of a telegram from India, dated the 27th September. The line from Bagdad to Hillah, and thence to Diwanyeh, on the Euphrates, is completed, but between the latter point and Korneh, where the Tigris and Euphrates unite with the Shat-el-Arab, there remain yet to be finished 160 miles of land telegraph to complete our through telegraphic communication with India. The Euphrates has ceased to be a navigable river for some years through the banks being neglected, and thus, until the land line is completed, the only communication between Bagdad and Bussora is by way of the Tigris, by the British-armed steamer, Comet, two Turkish steamers, and a steamer belonging to Messrs. Lynch, of Bagdad, which run regularly up and down the river; another steamer was about to be placed on the river, when I was there in May last, but I am not sure whether this has been done. The passage up the river, including stoppages for taking in wood, occupies from five to six days, according to the state of the river, the passage down the river being done in two days and a-half; this will account for messages of the 27th ultimo from India being reported on the 3rd instant. The delay between Bagdad and Constantinople, from the 3rd to the 7th of October, is owing to the temporary interruption of the land line passing through Mossul, Diarbekir, Sivas, and Angora. Another route from England to India, in connexion with the Persian Gulf cable, passes through Russia by way of Tiflis to Teheran, thence to Ispahan and Shiraz, and joins the cable at Bushire. The whole of this length will be completed in a few weeks. We shall then have two distinct routes to India —one by way of Turkey, the other through Russia. The Indian telegraphs, which connect together Calcutta, Bombay, Madras, Delhi, and all the principal towns in India, are now advanced eastwards as far as Rangoon, and the routes thence to China and to Australia, by way of Singapore, Java, and Timor, are almost entirely in comparatively shallow water, so far as the submarine part of the line is concerned, and do not otherwise offer any difficulty which should prevent our having daily telegrams from Hong Kong,

Melbourne, Sydney, Adelaide, and Brisbane, within three years from this date."—On the 12th instant, "C," an anonymous correspondent of the *Times*, thus comments on the foregoing communication :—"In a letter in the *Times*, signed 'Charles T. Bright,' I read the following paragraph, very strange, indeed, as coming from a professional engineer of long experience:—'The Indian telegraphs, which connect together Calcutta, Bombay, Madras, Delhi, and all the principal towns in India, are now advanced eastwards as far as Rangoon, and the routes thence to China and Australia, by way of Singapore, Java, and Timor, are almost entirely in comparatively shallow water, so far as the submarine part of the line is concerned, and do not otherwise offer any difficulty which should prevent our having daily telegrams from Hong Kong, Melbourne, Sydney, Adelaide, and Brisbane, within three years from this date.' Now, in my opinion, it would be difficult to comprise a greater amount of error in so small a compass than is contained in this short passage. The engineer, it is certain, has been drawing most abundantly on his imagination, and I fully expect to find him, by and by, promising to waft daily 'sighs from India to the Pole.' It is true that telegraphic communication has been established over India, and that it extends as far as Rangoon, but not a foot of this is submarine; all is by land save the passage of rivers. The sphere of our engineer's project, reckoning from Rangoon, extends over 60·50 degrees of latitude and about as much of longitude; but this is far from conveying an adequate notion of the grandeur of the scheme. From Rangoon to Singapore the distance is about 1,000 miles. If the telegraph in this case be by land it will be carried through an almost uninhabited jungle, and over the country of five independent and rather barbarous princes; if by sea, the cable will be laid for the most part in a coral bottom. From Singapore to Hong Kong the distance is about 1,500 miles, or about three-fourths of the breadth of the Atlantic, and here the telegraph throughout must be submarine, and not in a comparatively shallow sea, but in one of very considerable depths, vexed by typhoons and with hardly a resting-place. If we turn to the remaining part of our engineer's project, the difficulties are incomparably greater. From Singapore to Batavia the distance is about 650 miles, and the sea is shallow enough; but then it has a coral bottom nearly throughout. The Dutch laid a cable here about three years since, which conveyed a few messages for a day or two, when it broke through the friction occasioned by the ever uneven coral bottom. It was repaired and it broke, and this over and over again, and the Dutch have given up the project as impracticable. From Batavia by Timor to Cape York, in Australia, the nearest occupied point of the continent, the distance may be computed at 2,500 miles, or by one-fourth greater than the breadth of the Atlantic between Ireland and Newfoundland. This is not a shallow sea, but, on the contrary, considered by experienced mariners, one of the very deepest in the world. I have not yet quite done with your 'poetical engineer,' although the easiest part of his task only remains for consideration. This consists in carrying a land wire from Cape York by Brisbane, Sydney, and Melbourne to Adelaide. The distance here cannot exceed 2,500 miles, or about twice as far as from Calcutta to Lahore, and there will be nothing to interfere with this part of the line, unless now and then a savage, ambitious of adorning himself or his squaw with a bit of wire, or pointing his arrow with a fragment of iron. To sum up, your imaginative 'engineer' will have to lay down sometimes among coral reefs, and sometimes in unfathomed sea, some 5,000 miles of submarine cable, and 2,500 of land wire, making in all a telegraphic line of between 7,000 and 8,000 miles long."

MISCELLANEA.

Gas Lighting by Electricity.—At the Bath meeting of the British Association, Professor W. B. Rogers, of Boston, Massachusetts, exhibited a novel arrangement for lighting a gas-burner, or many gas-burners, by an electric spark, formed by drawing out a stopper of vulcanized iron. The friction sends a current sufficiently strong for the purpose.

French Rewards of Genius.—A few weeks since we announced that M. Rhumkorf had received the prize of 50,000 francs, offered by the Emperor Napoleon, for his induction coil. Honours are being freely bestowed in France, and among other tributes to genius we may mention that Mr. Sorel has been awarded the prize of the Marquis d'Argenteuil for his invention of the process of zincing iron, an operation better known as galvanizing iron.

British Capital.—From the Board of Trade returns we gather that the miscellaneous companies, such as telegraph, steamship, discount, financial, or others—all, or nearly all, of which are "limited," and of recent creation—have absorbed a paid-up capital of £37,000,000 sterling.

Payment of Dividends out of Capital.—Baron Martin said, in a recent case tried at the Guildford Assizes, "The law directs that directors may, with the sanction of the company, in general meeting assembled, declare a dividend to be paid to the shareholders, in proportion to their shares; but no dividend should be payable except out of the profits arising from the business of the company; and therefore it is the bounden duty of the directors—indeed, I do not believe that the shareholders could legally, make a dividend, for it is the directors who are to make it—it is their bounden duty, if a dividend is declared otherwise than out of profits, to refuse to pay it, and, if necessary, to appeal to the Court of Chancery to restrain its payment."

The Continuance of Parliament.—The present Parliament was "begun and holden on the 21st May, 1859," and will not legally expire until the close of next year. The last was the sixth session, and, as Parliament is septennial, "seven" can be holden. According to the usual practice, the dissolution will take place next spring, when we hope the friends of telegraphy will bestir themselves, and secure the election of some qualified representative of their interests in Parliament.

To Varnish Articles of Iron and Steel.—Dissolve ten parts of clear grains of mastic, five parts of camphor, fifteen parts of sandarach, and five of elemi, in a sufficient quantity of alcohol, and apply this varnish without heat. The articles will not only be preserved from rust, but the varnish will retain its transparency, and the metallic brilliancy of the articles will not be obscured.

The Electric Light.—At the Royal Institution ten years ago, Dr. Frankland gave a sketch of the condition of artificial lighting. Since that period but little progress has been made towards perfecting those processes of producing artificial light at that time in general use. Nevertheless, the improvements effected in the production and application of the electric light, the increase of our knowledge both of solar and terrestial light, and especially the discovery of an entirely new illuminating agent, threatening to produce a revolution in lighting almost equal to that which was the result of the invention of gas—rendered it desirable for the author again to review this subject after the lapse of a decade. In glancing at the improvements effected in the different departments of artificial illumination, those which relate to the electric light were first noticed. The electric light is produced by the interruption of an electric current flowing through good conductors; by this interruption the current is made to leap across a space provided in its circuit. The boundaries of this space, in the ordinary electric light, are formed by two portions of gas carbon, and during the passage of the electric current across it, the two pieces of carbon are heated to a most intense degree, and far beyond that produced by any other means at our disposal. The great source of illuminating power was shown to be the ignited ends of these two pieces of gas carbon, and not the space between them. Such being the nature of the electric light, the principal improvement which has been effected in it, during the past ten years, consists in the production of the electric current through the intervention of heat and mechanical force, by what is termed magneto-electricity. More than thirty years ago, Mr. Faraday produced a spark from the ordinary permanent magnet. Here, said the speaker (producing a magnet) is the very cradle of this magneto-electric light, and this is the very magnet with which Mr. Faraday operated. This improvement constitutes one of the greatest steps in advance which have been made in the application and production of the electric light. By the combustion of coal a certain amount of mechanical power is obtained, which is applied to the rotation of masses of iron in the neighbourhood of very powerful permanent magnets. In this way, currents of electricity are produced, and these are thrown together, and made to circulate through a system of conductors: in fact there is no difference, as regards the effect at the carbon-prisms, between the action of this magneto-electric current, and the ordinary electric current produced by the chemical action which takes place in the voltaic battery. But this improved mode of producing the electric force demands less manual labour; the mechanical work being performed by a steam engine, which causes the rotation of the armatures. This magneto-electric apparatus, as perfected by Mr. Holmes, has now been in use for upwards of two years in the South Foreland and Dungeness lighthouses, where, as well as in other similar beacons, the production of a light of the greatest intensity is of the greatest importance to the mariner. During this time it has performed its office remarkably well, and without a single instance of failure; thus proving itself well adapted for the purposes of lighthouse illumination. For domestic light it has not yet been brought into use; its expense, doubtless, at the present moment, being far too great to admit of its being employed in this way: but where a light of great intensity, regardless almost of the question of expense, is required, as in the case of lighthouses, this magneto-electric light can scarcely be too much prized. The speaker also described the mercurial electric light, but considered it inferior both in brilliancy and steadiness to that procured by the passage of the electric current between carbon terminals. More than thirty years ago, Mr. Faraday pointed out a source of the electric light in the permanent magnet; but we are only now beginning to use it for illuminating purposes. The brilliant little spark was long looked upon as a mere scientific curiosity, and is only now beginning to flash across the sea, guiding the mariner safely into harbour, or warning him from approaching a dangerous coast. How long will thermo-electricity have to wait before it receives a similar application? In thermo-electricity we have a direct transformation of the force of heat which we obtain with such great economy from coal, into an electric current, and this, by further education and development, might be rendered available in the production of the electric light. Hitherto, its application in this direction has been altogether unheeded, and yet of all sources of the power necessary for the electric light, thermo-electricity evokes this power most directly from coal. In the magneto-electric light we have the great disadvantage, that the heat of burning coal must be first transformed into mechanical power, which is made to rotate the armatures of magnets, and thus produce the necessary electric current. In this transformation of heat into mechanical power there is no less than $\frac{9}{10}$ths of the original force in the coal absolutely lost. Hence the advantage which would result from the direct application of heat to the production of the electric current.

Investigations on Molecular Physics.—Mr. Warren de la Rue, Mr. Balfour Stewart, and Mr. Loewy, are engaged in a series of important investigations, embracing a variety of interesting views connected with the physics of the sun; these views being derived partly from a discussion of the photographic pictures obtained at Kew, and partly from considerations wholly distinct from the results of photographic observations. Mr. Carrington has, also, recently placed at the disposal of these gentlemen his observations made at Red Hill, during a period of seven years. It is expected that some light may thus be thrown on terrestrial meteorology, and possibly also, on molecular physics, by the labours of these ardent workers in science.

Annealing.—In a considerable number of instances, bodies which are capable of undergoing ignition, are rendered hard and brittle by sudden cooling. Glass, cast-iron and steel are the most remarkably affected by this circumstance; the inconveniences arising from which are obviated by cooling them very gradually, and this process is called "annealing." Glass vessels are carried into an oven over the great furnace called the leer, where they are permitted to cool, in a greater or less time, according to their thickness and bulk. Steel is most effectually annealed by making it red-hot in a charcoal fire, which must completely cover it, and be allowed to go out of its own accord. Cast iron, which may require to be annealed in too large a quantity to render the expense of charcoal very agreeable, may be heated in a cinder fire, which must completely envelope and defend the pieces from the air till they are cold. The fire need not be urged so as to produce more than a red heat; a little beyond this, bars and thin pieces would bend if destitute of a solid support; and would even be melted without any vehement degree of heat. If it be required to anneal a number of pieces expeditiously, and the fire is not large enough to take more than one or two of them at once; or if it be thought hazardous to leave the fire to itself, from an apprehension that the heat might increase too much, the following scheme may be adopted: heat as many of the pieces at once as may be convenient, and as soon as they are red-hot bury them in dry sawdust. Cast-iron, when annealed, is less liable to warp by a subsequent partial exposure to moderate degrees of heat than that which has not undergone this operation. The above methods of annealing render cast-iron easy to work, but do not deprive it of its natural character. Cast-iron cutlery is, therefore, stratified with some substance containing oxygen, such as poor iron ores, free from sulphur, and kept in a state little short of fusion for twenty-four hours. It is then found to possess a considerable degree of malleability, and is not unfit for several sorts of nails and edge-tools. Copper forms a remarkable exception to the general rule of annealing. This metal is actually made softer and more flexible by plunging it, when red-hot, into cold water, than by any other means. Gradually cooling produces a contrary effect.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2456. F. Tolhausen, improvements in apparatus for transmitting signals.—A communication.
2461. W. Anderson, improved apparatus for working railway signals.
2463. F. W. Shields, improvements in telegraphic posts.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1720. R. A. Brooman, improvements in batteries and in electric printing telegraphs.—A communication.
2250. W. Chubb and S. Fry, improvements in the means or method of effecting communication between passengers, guards, and engine-drivers of railway trains.
2254. A. Bertsch, improvements in lightning conductors for preventing atmospheric electricity damaging electric telegraph instruments.
2256. M. L. J. Lavater, improvements in the manufacture of driving straps or belting, and of tubes of vulcanized india-rubber, and also in the manufacture of the helical coils of wire commonly inserted in vulcanized india-rubber tubes, also in desulphurizing articles of vulcanized india-rubber.
2260. T. H. Simpson, improvements in printing by electricity for telegraphic and other purposes.
2312. F. Hovenden, improvements in railway signal apparatus.
2341 A. V. Newton, improvements in the mode of and machinery for manufacturing telegraphic cables.—A communication.

PATENT SEALED.

113. J. H. Simpson, certain improvements in printing from type by electricity.

PATENT WHICH HAS BECOME VOID.

2429. M. Theiler, improvements in telegraphs.

NOTICES TO PROCEED.

1405. W. H. Preece, improved domestic telegraphic apparatus.
1412. H. A. Bonneville, improvements in telegraphic printing apparatus.—A communication.
2254. A. Bertsch, improvements in lightning conductors for preventing atmospheric electricity damaging electric telegraph instruments.

TO CORRESPONDENTS.

L. A.—We have received no reliable information of the failure of the cable you mention.

Une Femme.—1. Yes, a great many. 2. If you possess a good physical constitution. 3. The climate of India is very trying to Europeans generally.

Alfred W.—Try the battery described by Captain Selwyn in No. 40 of our journal.

Utopian.—We must confess to little faith in the statements of persons who affirm that they can convey intelligible signals by means of the electric current without an artificial conductor. When we see we will believe.

Londonensis.—The head offices are situate 58, Threadneedle-street, E.C.

Enquirer.—You will get the work through Messrs. Trübner, the American booksellers, of Paternoster-row.

J. Roberts.—We have heard it reported that the Indian Government intend to employ a large number of female telegraphists, but we are not in possession of any reliable facts relating to the subject at present, although we have made inquiries of several parties connected with Indian and home telegraphy.

Archimedes.—We shall shortly insert a full description of Mr. Preece's electric semaphore. We are informed that the arrangement has answered the purpose well on the line upon which it has been adopted.

Peter I.—We do not think that the plan you suggest for effecting communication between the guard and engine-driver could be successfully applied; it is too complicated, and would be liable to get continually out of order—a very serious defect.

B—t's promised contributions will be most acceptable.

A Constant Reader.—The magnesium wire can be purchased at any of the photographic establishments, we believe, in town or country. It can be had of any length and dimension.

D. M. E.—The engineers of the Persian Gulf line are Messrs. Bright & Clark, of Victoria-street, Westminster.

Experimentalist.—We are not able to furnish you at present with the progress made in the manufacture of balata, but we believe that extensive experiments are being carried on to test its applicability for submarine insulation.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before Seven o'Clock on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	1 7 6
Half ditto	2 10 0	Four lines and under (single col.)	0 3 0

Single Advertisements from the country must be accompanied with stamps in payment.

POPULAR NOTIONS OF THE TELEGRAPH.

THE time is not so far distant when it was believed that the electric telegraph was a carrier of goods as well as messages. Every one is familiar with the story of an elderly lady who hung her umbrella on the wires, and expected to see it whisked off to a distant relative. Many laugh at the old lady's simplicity who are equally uninformed of the operations of the telegraph, and who will not give themselves time to make a few inquiries into the laws by which electricity has been made to obey our behests. Professor Faraday declared, "there was a time when I thought I knew something about the matter, but the longer I live, and the more carefully I study the subject, the more convinced I am of my total ignorance of the nature of electricity;" yet this is the agent we employ to run on our errands. Notwithstanding the foregoing confession, which is characteristic of a man who believes that "there are more wonders in heaven and earth than are dreamed of in our philosophy," we do not despair of arriving at conclusions which shall establish the value of electricity as an illuminator and as a motive power, surpassing in its uses to mankind the services of gas and steam. Knowledge has, within the past few years, increased; observation has been strengthened by research; and there is abundant reason to hope that, ere long, discovery and invention will open up new spheres wherein the subtle fluid may be employed advantageously.

Our present object is not to enter upon an exposition of the wonders of science, but rather to note a few of the popular fallacies concerning electricity in its application to telegraphic purposes. A few years ago a leading (?) article appeared in a daily newspaper, which shows at once the ignorance of even journalists, who are supposed to know something of a subject on which they essay to express an opinion. The editor of the paper thus referred to comments on the projected line of telegraph between Dover and Yarmouth in the following strain:—

"It is a fact, which some of our readers may be ignorant of, that sparrows and other small birds which happen to perch on those mysterious lines of communication, the telegraph wires, are destined ever and anon to suffer severe shocks of electricity, the effect of which is (though we never witnessed the phenomenon) that they drop down, not dead, but half dead with amazement and terror. The shock, if severe enough, will destroy them. Electricity can be administered in doses which would kill a horse. Perhaps, by transmitting through the telegraph wire a very powerful charge, the unhappy sparrows along the whole line from London to Yarmouth might be cut off. This, in case of necessity, or as a matter of cruel curiosity, might be employed as a means of getting rid of these vermin. It is not uncommon or extraordinary to see at least a hundred of these feathered depredators on one mile of wire. The length of the whole line of which we speak is 146 miles. A shock strong enough to destroy sparrow-life would, with these data, cut off from the land of the living, at one fell and fatal swoop, not less than 14,600 of these little creatures. One thousand miles of railway would in like manner, with the same conditions, be the death of 100,000. Even supposing that death does not ensue, yet how miserable will be the state of these little animals when the whole island is covered with a veritable network of telegraphic wires! Fatal twigs these for tiny feet! The whole family of sparrows will be paralyzed. The fowls of the air will be electrified. People, as they talk with each other, and whisper to each other in unheard communion, at the distance of 1,000 miles, will be causing serious inconvenience to the feathered race. We tremble to think of the consequences, and heartily recommend the case to the Society for the Prevention of Cruelty to Animals. Dog-carts sink into insignificance when compared with this wholesale palpitation—this universal twittering and consternation—among the feathered tribes. How many a sweet song will be interrupted—how many a little throat silenced—very suddenly indeed, when this mischievous machinery shall be brought into universal play!"

It will be unnecessary at the present date for us to state that this specimen of "leading" literature is founded on an erroneous conception of electrical laws. No bird could be affected in the slightest degree by the electric current if perched on a telegraph wire, unless, as is very improbable, its body was in connection with the earth at the same time. Here we have an exemplification of the folly of the blind leading the blind. This article made many people, equally simple as the writer, "tremble to think of the consequences to the feathered tribe." One of the odd notions entertained by the public on the introduction of the over-house telegraph was, that messages in the course of transit from station to station occasioned a noise as of the humming-bee. A lady, who gave permission to the engineer of the London District Telegraph Company to erect a telegraph pole on the top of her house, subsequently complained to the secretary of the company of the horrid discourse of young men at work on the telegraph in the small hours of the morning, who were described as using language "unfit for any respectable female to listen to." The horrid discourse which so much annoyed this good lady was caused by the wind whistling through the wires and causing their vibration. A less imaginative person could simply hear the humming sound before referred to.

Happily, these erroneous views and prejudices are giving place to a more enlightened conception of the uses of the telegraph; and its importance as a means of communication is daily becoming more apparent. It is not long ago, however, that an individual presented himself at the telegraph-office at Dover one afternoon with a sum of money in his hand, and desired the clerk to send the cash *in propria formâ* up to London by telegraph, to be forwarded to a certain banker's establishment. The money was to take up a bill due that day, and there was no time to send it by train. He seemed perfectly surprised that it could not be sent. At the London terminus of the South-Eastern Railway a servant came to the office heated and out of breath, with a small parcel to be sent by telegraph to a distant part of the country. It appears he had instructions to send it by the train; but he arrived just one minute too late, and as it was of consequence, he thought he could get out of his dilemma and expedite matters by adopting this course. The telegraph is often mentioned as auxiliary to the railway system, and hence possibly the impression evidently entertained by the unfortunate domestic, that it is only when the locomotive is found to be too slow or too fast that the telegraph should be employed. These cases occur but seldom, and if proper means were used by the managers of telegraph companies to disseminate useful information concerning the telegraph—its uses, advantages, and economy—a more general employment of the wires might reasonably be anticipated. All, or at least many, commercial men of the present generation have great faith in the quaint couplet—

"He who in the world would rise,
Should take the papers and advertise,"

and right well obey the injunction it enjoins. In the management of telegraph companies there appears much of the "penny wise and pound foolish" system. A deep-rooted antipathy, arising from ignorance, exists towards the electric telegraph; the uninformed invariably associate it with thunder and lightning, and conceive the offices to be as dangerous of approach as gunpowder magazines. Familiarity may breed contempt, but unfamiliarity engenders fear; hence measures should be

adopted to assure people that the mysterious-looking cases which they sometimes see at railway-stations, and which have been described as combinations of the beer-engine and the eight-day clock, are but simple pieces of mechanism, and that no danger need be apprehended from their employment. A little treatise on the telegraph in the form of a handbook would do much towards setting doubts and fears at rest, and prove an effective medium for advertising tariffs or other information concerning the business of a company, and its claims to public support. A step in this direction was taken by the London District Telegraph Company in the beginning of the present year. Thousands of copies of a pocket calendar were circulated, and if it is not a consequence of this course, it is certainly a fact that the balance-sheet of this company for the half-year ending the 30th of June last, compared with the accounts for the corresponding period of 1863, shows a marked improvement in the receipts arising from general business. These efforts should be multiplied, and the public, from the Land's End to John o' Groat's, should be made as familiar with the telegraph as they are of cheap excursions to the sea-side.

THE AWARD OF FIFTY THOUSAND FRANCS TO M. RUHMKORFF.

It has been previously announced in these columns that M. Ruhmkorff had gained the prize of 50,000 francs, offered by the Emperor of the French for the best application of electricity. The prize was originally offered in 1852, and its award entrusted to a commission composed of the following gentlemen:—M. Dumas, senator, President; MM. Pelouze, Regnault, Rayer, Serres, Becquerel; Baron C. Dupin, Baron Ségnier, General Morin, General Piobert, and H. Sainte-Claire Deville, all members of the Institute; M. Reynaud, inspector-general of roads and bridges, and chief of the lighthouse service, and M. Jamin, Professor of Physics of the Faculty of Sciences in Paris. The report of this commission has been published in the *Journal de l'Industrie du Commerce*, and contains some very interesting information.

In 1858 the commission proceeded to the award, and came to the decision that there was no application of sufficient importance to warrant the disposal of such a prize, but petitioned the Emperor to allow the offer to stand good for the next period of five years. The present report announces a notable improvement in the application of electrical power, and awards the grand prize to M. Ruhmkorff. M. Froment has been raised to the grade of officer of the Legion of Honour, at the suggestion of the commission.

In the third place the commission recommend the repetition of the offer of the prize of 50,000 francs, and this recommendation has been acceded to by the Emperor. The report of the commission is from the pen of its President, M. Dumas.

M. Ruhmkorff, it appears, was formerly a workman in the employ of some of the best instrument-makers in France, became afterwards a manufacturer on his own account, and finally head of one of the first establishments in Europe. He is essentially a self-educated and self-made man, and, in the words of the report, "worthy to serve as a model to the many intelligent workmen engaged in the manufacture of instruments of precision."

After referring to the discoveries of Ampère, Œrstedt, and Faraday, the report goes on to say:—Every time that the electricity of the pile comes into contact with a conducting-wire and produces a current therein, every time that the communication and the current are interrupted, the phenomena which are produced are not confined to such transmission or interruption of the current. The bodies in the neighbourhood of the conductor are influenced. If the wire which receives the current is wound round a bobbin, and this in its turn is enveloped in another bobbin of uncharged wire, each time that a direct current is created or interrupted in the former, a current is produced in the latter in the contrary direction. In multiplying these interruptions or in rendering them more frequent, the inductive coil becomes an electrical apparatus of a special and novel kind, and presents phenomena which resemble those of the plate machine. From the year 1851 M. Ruhmkorff has devoted himself to the construction and perfecting of such apparatus; and he has succeeded in giving his name to it, in raising it to importance in a scientific point of view, and in endowing it with an amount of energy which fits it for the basis of serious applications. The apparatus of Ruhmkorff, then, combines the two forms of electricity which were separated by a long interval, that of the frictional machine and of the pile. The effects of the Ruhmkorff apparatus are well-known; it can be charged almost instantaneously, its spark inflames combustible substances, melts metals and the most refractory minerals, and reproduces all the effects of lightning, and pierces without difficulty masses of glass four inches in thickness.

Electricity can now be employed to illuminate glass tubes in such a manner as to be highly useful in mines, or other places where there is danger of explosion; under water, for divers; and in surgery, for throwing light into the mouth or other parts, without producing any sensation of heat. The Ruhmkorff apparatus has been found particularly useful for marking the instant of the departure of projectiles and that of their striking any object, and thereby measuring their velocities. Five hundred have been constructed expressly to inflame the gas used in the Lenoir gas engines, and it is in everyday use in quarries, tunnels, and other situations for the firing of trains of powder, for which its regularity of action, its great power, and the distance through which it operates, render it peculiarly adapted. The few elements which it requires, stated at three in lieu of a hundred, and its capacity for firing eight or ten trains or mines at the same instant, are also great additional advantages. In 1858 it was employed with great success by Lieut. Trève, of the French navy, in the removal of the bars formed in the lagunes of Venice; and in 1860 it was with it that the principal fort of the Peïho, in China, was blown up by the firing of eight mines simultaneously, and that the strong iron stockades were cleared from the bed of the river.

The report dwells at considerable length on the application of electricity in the mechanical arts, for purposes of illumination in electro-metallurgy and in surgery.

With respect to the first of these divisions, the report says, that notwithstanding the great improvements that have been made, the "electric-horse" costs, at present, twenty or thirty times more than the "steam-horse," and that, "as a motor for works requiring power, electricity is therefore yet far from supplying a substitute for steam." But there are many cases in which it is serviceable, such, for instance, as in the Lenoir machine, in which the sudden ignition of gas causes an instantaneous elevation of temperature, first on one side of a piston in a cylinder and then on the other, and thus creating a motor; or for producing, at a given moment, and at a distance, the movement of light mechanical appliances which direct the action of other parts moved by powerful mechanical means, acting in this latter case after the manner of the nervous system in animals, which transmits the orders, and leave to the muscles the task of carrying them into effect. In this way it has been used to throw into action the brakes of railway carriages, causing the impetus of the wheels themselves to retard their own progress; and, acting on the same principle, experiments have been made with the view of making steam boilers feed themselves spontaneously.

Reference is made also to the engraving of rollers by means of a design drawn with non-conducting ink on metallic paper; to the copying of a design from one roller on another, as in the machine of M. Gaiffe; and to the pantographic apparatus of M. Cazelli, which is described as capable of transmitting from one end of France to the other despatches in any language whatever, tracing drawings, or whatever is delineated on a sheet of metallic paper prepared for the purpose, and reproduced on another paper rendered chemically impressionable to the electric current; to the weaving machinery of M. Bonelli, which, although not found to succeed in complicated work, will, it is expected, be eventually applied usefully in other cases.

"But," says the report, "it is in those cases in which the mechanician desires to transmit a feeble force to a great distance, as it were, with intelligence and exactitude, that electricity stands at present without a rival," and it is thus that it is so eminently adapted to telegraphic purposes. M. Dumas dwells very emphatically on the system of Professor Hughes, which is explained at length; and, looking at the inconceivable rapidity of transmission which is obtained by it, the learned reporter believes that if to the combinations of Professor Hughes were added the celerity of finger of a pianoforte player, there seems no reason why a reporter should not be able to transmit a speech to Strasbourg, Marseilles, and Bordeaux, while it is being spoken in Paris.

The commission, however, properly points out that the practical application of the wonderful powers of electricity depend greatly

on mechanical exactitude, and says that the combinations of MM. Bonelli, Cazelli, and Professor Hughes remained in the condition of mere experiments until M. Froment, a manufacturer of instruments of precision in Paris, undertook their construction.

As regards illumination by electricity, the report commences with a reference to the extraordinary combinations and experiments of Sir Humphrey Davy (after whom it may be mentioned, *en passant*, a street has just been named in Paris), with a pile of 2,000 elements, having a superficial area of more than a hundred square yards, and which M. Dumas himself repeated thirty years since in his public lectures, and then refers to the Bunsen pile, which contained but thirty elements, and to the many unsuccessful experiments made to light towns by electricity, an attempt designated as a mistake, on account of the fact that the value of electric illumination is in great single lights, which are unsuitable to purposes where dissemination is required. Reference is made to the application of the hard residue of the gas retort in place of charcoal; to the production, by M. Jaquelin, of the Paris School of Mines, of an artificial substance purer and cheaper than the former; to the arrangement of M. Léon Foucault, by means of which the light itself regulates its conductors; to Mr. Staite's invention for the same purpose; to M. Serrin's self-lighting regulator; and lastly to the new apparatus invented by M. Foucault, which M. Dumas considers the best yet produced.

The report then arrives at the application of dynamic electricity to the same purpose, and details the results that have been arrived at by means of the scientific apparatus of Pixü, as applied, in Belgium, by Nollet to practical purposes. A Parisian company, the "Alliance," has applied a modification of this apparatus with perfect success in the slate quarries of Angiers, in the workshops of the railway of the north of Spain, and many other places. The most important application, however, of the kind has been made at Havre, an electric light having been placed on Cape La Hève, near a light-house of the old kind of the first order. A comparison of the two gives the following results:—The light of the latter is equal to 600, and that of the former to 3,000 carcel lamps, the cost of the oil-light being equal to seven centimes for each unit, while that of the electric light is rather less than two centimes, the expenses of the light-house and the interest on the capital engaged all included.

The report gives special praise to M. Oudry for his galvanoplastic work on cast and wrought iron, and the Emperor has rewarded M. Oudry with the Cross of the Legion of Honour.

With respect to medical electricity, the report alludes to the success which Dr. Duchenne, of Boulogne, has met with in the treatment of chronic affections of the nerves and muscles, and to one hundred and forty cases, reported by M. Middeldorf and other surgeons, of the successful treatment of polypi and tumours, by by means of platinum wires heated by electricity.

In the conclusion to the report, M. Dumas says, as the chemist declares that there is neither creation nor loss of matter, so the philosopher maintains that there is neither creation nor loss of power; heat, light, magnetism, and electricity are but manifestations of various conditions of an ether in movement, and are transformed one into the other with the utmost facility. Of these forces, electricity has been the most recently studied, and its properties are still the most mysterious, notwithstanding the grand discoveries which have been made. It may be said, in fact, from the observations made since the commencement of the century, that of all the manifestations of the movements of the ether, those which give rise to electrical phenomena are at once the most delicate and the most fruitful.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XII.

A.D. 1810, July 18.—No. 3363.—Stebbing, George.—"Certain improvements on the action and other parts of sea and land compasses," consisting of:—1st. For "the metal or steel" "center or point" that supports the card is substituted "a ruby, jewell, precious or any other hard stone or composition" set in metal, and long enough to bring the card near the centre of gravity. 2nd. For the "tap" or "bottom of the cap," "hard metal" or stone is substituted for agate. "In the center thereof is sunk the section of a small circle or sphere, well polished, to receive the head of the ruby" that supports the card, "instead of the socket in the agate, as before used." 3rd. The ends of the magnetic needle are made square, "by reducing the width of the needle to its thickness." 4th. "In time of action or very bad weather," the card and needle are suspended by a silk thread, "about one quarter of an inch off the center, hung from the glass by means of a swivel or hook" "to the top of the cap, or from a piece of metal put across the kettle or bowl;" "and at the bottom of the cap, under the card," "a piece of tube about an inch long, in a conical shape," is placed, so that the card will neither touch the side of the kettle nor be thrown off the centre. Or the compass may be suspended "with elastic springs."

A.D. 1810, August 14.—No. 3371.—Whitmore, William.—"The magnet toy, to facilitate the teaching of children to spell, read, and cypher in any tongue, with ease to the teacher, pleasure to the learner, and proportionate expedition." This toy consists of a box (containing mechanism) having depicted on its upper surface "either the letters of the alphabet, numerals, types, symbols, or musical notes, according to the views of the teacher," arranged in a simi-circular form, somewhat like the plate of a dial; an "index," revolving about the centre of the dial, carries a horse, "or other captivating, whimsical, or attractive device;" at the pleasure of the teacher the horse is made to take up any loose duplicate letter or sign laying on "another concentric, &c., exterior, semi-circular, inclined rim," opposite to those on the dial, and to deposit it on a flat simi-circular rim, which occupies the remaining half-circle to that from which the duplicates are taken; the horse also nods, shakes his head sideways, and has other motions at the will of the operator. The horse's head is balanced by a weight concealed within the body, and acted on by a string from the front of the box, passing through the hollow index centre and the leg, so that on its being pulled the horse's head is depressed, and a magnet placed in his mouth is brought into contact with a piece of iron on the duplicate; on releasing the string, the concealed balance weight raises the horse's head; another string, having its two ends projecting from the front of the box, passes round a pulley on the index axis and turns the horse round; the head is then depressed, the duplicate strikes against an upright ridge, and is deposited on the rim. Another method of moving the horse is described and shown, in which a handle connected with a shaft and pinion moves a crown wheel on the index axis; levers, rods, and tubes give motion to the horse's head.

A.D. 1812, January 23.—No. 3525.—Rowland, Richard.—"Certain improvements in ship's steering wheels, compasses, and binnacles, and in the mode of lighting the same." A binnacle is described and shown having three compartments in the upper part. A compass card is in each of the end compartments, respectively "suspended" on metal centres fixed to the bottom of the compartment. Each compartment has a door and "wings" on hinges, so as to protect the vertical glass over the compass; also a skylight, over one of which a rule and "a pair of lights" [sights?] is fixed to ascertain the "bearings of any object seen." The centre compartment contains the light, which can be drawn up close to the compasses, and is minutely described. Rollers and curtains exclude the light when necessary, and a "time-glass" is fixed "on a center" at each end of the binnacle. "When the glass comes to an upright position the compass card is about one foot in diameter." The cap of the storm compass "is fixed under the card, so that the center of suspension is in the plane of the upper surface of the card." "The lubber's line is on a swinging pendulum" whose fulcrum is "in the plane of the center of suspension of the card." The lower part of the binnacle has three compartments, the two outside ones are cupboards, and the centre one contains a "dripstone" cemented into a pan without a bottom, thus forming a bottom to it. When the steering wheel is mounted fore and aft, instead of athwart ship as heretofore, a square binnacle is used with a "lighthouse" at one corner. The cards are viewed in a similar manner to that of the former binnacle; they are, however, transparent, and placed one underneath the other. The light is lowered and raised by a cord, and lights the cabin as well, the bottom of the binnacle being glazed. Various compasses are described with centres fixed in the bottom of the box, with or without "gimbols." The box is filled with spirits of wine. A method of preserving candles is also described, by dipping the wicks into melted tallow, and packing them in a vessel of water, oil, or spirits, or in a water-tight case in a vessel of water.

A.D. 1813, January 30.—No. 3644.—Crow, Francis.—"Certain improvements in the mariner's compass or boat compass." This compass has a "card or index that floats in alcohol contained in a metallic bowl, suspended by gimbals." "The card or index of this compass is constructed of two concave metallic plates, which

are hermetically sealed or soldered together, forming a lens, within which is contained and firmly fixed a magnetic needle." A glass plate confines the liquid in the bowl, and permits the card to be seen; in the centre of the inside of the glass plate a metallic point is cemented, which projects downwards into "an inverted hollow cone" fixed on to the centre of the upper part of the card; to the centre of the under part of the card a weight is attached, keeping it in an horizontal position and "adjusting its pressure on the point of action." To stop the vibratory motion of the bowl, a "rod" is attached to the centre of its external surface, having "a tender spring, which is received by a concave metallic dish attached to the compass box underneath the said bowl, on the surface of which dish the said spring freely acts." Another method of stopping the vibration of the bowl is described and shown:—"A segment of a sphere (the radius of which arises from the line of suspention) is attached to the inferior side of the said bowl, acting against the extremity of a tender spring arising from the side or other part of the compass box." A "spring valve" admits the escape of expanded air in a hot climate. The alcohol is replenished by means of a chamber round the upper part of the bowl.

A.D. 1813, February 4.—No. 3646.—Alexander, George.—"An improved mode of suspending the card of the mariner's compass." The agate cup, receiving the steel point on which the needle is free to move horizontally, is suspended by gimbals; also the point on which the needle moves is suspended by gimbals. This is accomplished by having a "fork" with "two prongs" stand up "perpendicularly" from "the bottom of the brass (or other suitable metallic) box;" "a gimble ring" is suspended by screws between the prongs, within which ring the agate cup is similarly suspended. "In the centre of the magnetic bar, on which the card is placed, there is a large circular opening to admit through the fork, at the north and south sides of which are fixed two small upright pieces of brass (or other suitable metal), holding between them by a screw from each a large gimble ring, on which gimble ring is erected at the east and west sides a gallows or arch of brass (or other suitable metal), in the centre of which, directed downwards, is the point which rests in the agate (or other substance) cup below. On the top of the gallows or arch there is placed a thin piece of concave brass (or other suitable metal) about one inch diameter, and in the centre of the glass, immediately above, is fixed a prong pointing downwards, which acts within the cavity of the brass (or other suitable metal) below."

A.D. 1813, November 25.—No. 3760.—Duncombe, John.—The title of this invention refers to all the improvements set forth in the specification, and is as follows:—"My invention and improvement, as hereafter described and applied to mathematical and astronomical instruments, in order to render them more portable, accurate, easy, expeditious, and certain in their application to topographical and nautical surveying, and the mensuration of celestial angles on land or sea, and for ascertaining the direct distances of inaccessible objects within a limited extent at one station only, without the usual or any other calculation. These inventions and improvements consist in a new index, which ascertains the measured quantity of an angle to any proposed rational degree of precision, by rendering the divisions of those minute parts hitherto imperceptable to the sences truly conspicuous and distinctly legible by the common naked eye; and an attached new parallel movement, by which the natural sine and cosine of such angle are at the same time precisely obtained to any eligible radius, without tabular or other reference; and also a detached new parallel movement, furnished with telescopic or other sights, by which the direct distances of inaccessible objects within a limited extent are accurately measured at one station without trigonometrical or other calculation; and a new improved compass, whose index points due north and south, and which is capable of adjustment according to the known or observed variation of the magnetic needle." The "improved compass" has "a brass or other non-magnetic index fitted to the cap of the magnetic needle, and which is capable of being always adjusted thereto, according to its known or observed variation from the meridian, and thereby caused constantly to point due north and south. This improvement is general to the compass of every description."

A.D. 1818, May 7.—No. 4259.—Jennings, Henry Constantine.—"An improvement in the mariner's compass, being a means of guarding or protecting the magnetic needle of it from all action arising from iron in its neighbourhood." The compass is "mounted and fitted up in the usual manner with gimbals, glass cover, wooden case, &c.;" but the needle card carries "four pieces of iron softened by annealing," two being "screwed to the card at each end of the needle," these "are intended to act as guards against the passage of the magnetic fluid, by absorbing the first quantity of it." Iron filings, carefully annealed, are made to surround the needle by being enclosed "between the sides and bottoms of the brass or copper boxes which enclose the needle and card;" the sides and bottoms of the boxes are kept exactly the same distance apart, truly circular, and flat; and "the needle card, &c.," is "suspended on a point accurately in the centre of the box." The "guards at the ends of the needle" are of thin sheet iron, bent so as to be concentric with the card centre when they are fixed, thus forming segments of a circle. The iron for the "guards," as well as the iron filings, are annealed "by being enclosed in a soft plate iron box, and intimately mixed either with alumine clay, in fine powder," or "an argillaceous iron ore;" the box is then "well covered with a soft plate iron lid," "exposed to a strong red heat," and let "remain in the oven or furnace until it is become cold," the powder is then separated from it. The kind of needle "used by the late Dr. Gowen" [Gowan?] "Knight" is preferred.

A.D. 1819, May 18.—No. 4374.—Atkins, George.—"An instrument for ascertaining the variation of the compass." This invention consists of:—1st. "Certain improvements in magnetic needles." Two steel wires or arms, having north polarity at their free ends, are affixed "to the south half of the needle, forming equidistant angles of about sixty degrees with the north end of the needle." Owing to the magnetic force to which the needle is subject being greatest when the needle is 90° from the meridian, it is believed that this needle will have greater magnetic force and steadiness than a needle of the usual construction. Another improvement in magnetic needles consists in making the needle, in vertical section, of the form of a "segment of a circle, or of an elipse, or of a polygonal figure, having a ring or aperture at bottom to admit the central point, and two horizontal ears at the ends, to which the card is attached." In this needle the magnetic fluid is in a vertical line near the extremities. 2nd. A collar (suspended at its centre on a pillar by gimbals) carries a dial, engraved as a compass card, and able to be set to any required point, either by a compass mounted on the cap of the collar, by the binnacle compass, or by one in another compartment of the same box. The collar has a limb, with a long and short sight moveable on it and on the dial, and a weighted hollow cone to balance the instrument. In another construction, the collar is balanced on a pivot, and carries an arm with "a vertical crotch," "having a slit or notch which slides freely (but without any shake) on a steel fixed to the side of the box." In a third arrangement, the central collar is suspended by external gimbals affixed to the box. A balance weight is attached. Also a cheaper form is described, in which a wooden dial plate is suspended to the box by gimbals, and one removeable sight is used.

A.D. 1824, August 5.—No. 4996.—Graydon, George.—The title of this invention is:—"A new compass for navigation, and other purpurposes;" but it relates to a "celestial compass," which is "adapted to obtain data for determining the latitude or longitude at sea by means of the heavenly bodies, and at a time when the horizon is obscured, and also of finding the azimuth of the sun or a star at any time when these objects are visible." This compass may also be used "in place of the ordinary magnetic compass," and for "ascertaining the variation of the magnetic needle." No magnetic needle is used in this compass; in obtaining "the moon's meridian, distance, and declination, as data for determining the latitude or longitude," however, it is directed to turn the instrument round upon a vertical axis until certain horizontal axes, and consequently a certain line, "is found, by the aid of the common magnetic needle, or any other convenient manner, to be somewhere near the plane of the meridian." Modifications of this instrument, and methods of adjusting it for use "by day when the sun is visible," "for steering a ship by means of the motions of the heavenly bodies, instead of steering by the magnetic needle," and for "taking bearings on land, or for laying down angles in surveying by means of the heavenly bodies, without using a magnetic needle," are described at length.

Advances by Directors for Necessaries.—If a company has incurred a debt for necessaries supplied to it, then, whatever may be the extent of its borrowing powers, any director or shareholder is justified in paying off that debt; and if he does so, he has, in equity, a claim to contribution from the other shareholders. This equity is, however, postponed to the claims of regular creditors of the company. This is the decision of Vice-Chancellor Wood, in the case of Lowndes *v.* the Garnett and Moseley Gold Mining Company of America (Limited).

THE EXTERNAL PROTECTION OF DEEP-SEA CABLES.

WE quote the following statement from the report of the late Submarine Telegraph Committee, as it will enable our readers to judge for themselves as to how far the Committee of the Board of Trade, and that of the Atlantic Telegraph Company, coincide in their views as to the best form of cable for deep-sea purposes:—We have ourselves made experiments upon several forms of cable specially devised by various persons for deep-sea lines. The following table gives a general view of the results. As one of the main objects to be attained is a minimum of extension with a maximum of breaking weight during the process of laying, we have compared the results by showing for each cable the equivalent length in water due to a definite elongation and to the breaking weight:—

NAME.	General Description of Arrangements for Strength and Protection.	Specific Gravity.	Length of Cable in Water in Fathoms equivalent to		
			0·5 per cent. of Elongation.	1 per cent. of Elongation.	Breaking Strain.
CABLES IN WHICH THE STRENGTH IS PLACED IN THE OUTER COVERING BY MEANS OF HEMP OR WIRES LAID ON SPIRALLY.					
			Fathoms.	Fathoms.	Fathoms.
Clark, L.	Steel wire, with a slight spiral, covered with tape, shellac, and marine glue	1·92	1,610 1,119	Not reached. Not reached.	Not broken. 3,376
Gisborne & Forde (Gibraltar deep sea)	Steel wires, coated with hemp, laid spirally	1·9	1,176 2,440	1,947 3,924	Not broken. Not broken with a weight =5,683 fathoms in water.
Siemens	Strands of hemp, laid spirally, protected by thin copper sheathing	1·5	1,842 2,046 1,694	2,552 3,672 3,284	Not broken. Ditto. Ditto.
CABLES IN WHICH THE STRENGTH IS PLACED IN THE OUTER COVERING BY MEANS OF HEMP OR WIRE LAID ON LONGITUDINALLY.					
De Bergue	Tarred hemp lines served round with cord of hemp	1·26	5,300 —	8,124 5,908	Not broken. 16,982
Godefroy	Steel wires, coated with india-rubber, and covered with india-rubber canvas	1·9	2,658	Not reached.	3,424
Ditto	Ditto	1·4	2,596 2,596	3,500 Not reached.	Not broken. 3,309
Hall & Wells	Hemp lines kept in place by plaited hemp	1·35	760	1,126	4,420 4 per cent. extension.
Ditto	Steel wire and hemp lines kept in place with plaited hemp	1·6	2,499	Not reached.	2,729

Ditto	Ditto, outer covering Godefroy's compound	1·3	3,835	6,340	6,348

As regards the liability of these cables to kink, we would observe that the Messrs. Gisborne & Forde's (Gibraltar) cable was easy to kink, and was set in kinks by tension. Messrs. Silver's cable was disposed to kink. Messrs. Clark's, De Bergue's, Godefroy's, Hall & Wells', Sinnock's, and Allan's were difficult to kink, and the kinks generally unfolded by tension.

A cable made by Mr. Hooper was submitted after our experiments were concluded, and we had no opportunity of testing it. The strength is given by steel wires laid on in a slight spiral, protected from corrosion by means of vulcanized india-rubber.

The results shown in the above table for Mr. Allan's cables are remarkable. In these cables the strength is given by steel wires laid spirally round the copper conductor, thus using the strength-giving material to form part of the conductor; the area of the conductor is therefore increased, and there is no danger of the conductor knuckling through the gutta-percha from the resiliency of the latter. This addition to the conducting area increases the induction of the cable in the full ratio of the increased area, but it only increases the conducting power of the cable in the proportion which the conductivity of steel bears to that of copper, which is about one-seventh. To obtain the same capacity for the transmission of messages in a cable of this kind as in a cable in which copper forms the sole conductor, the dimensions of the conductor must be increased to give the same ratio of conduction to induction. The insulating material of course requires protection in these as in other cables.

All the cables in the table in which iron is used for strength have been furnished with some protection against corrosion. This is afforded in some cases by hemp; in another case by tape, shellac, and marine glue; in another by india-rubber and india-rubber canvas; in another by a mixture of cocoa-nut and gutta-percha covered by india-rubber canvas.

In the cables in which hemp is used for giving strength, the hempen strands have been protected in one case by a serving of hemp, in another by a combined covering of hemp and iron wire, and in another by a sheathing of copper. The object of employing copper being, that it is not so subject to corrosion in the sea as iron.

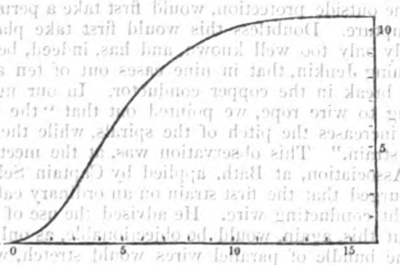
We consider it essential that in iron or steel covered cables the iron or steel should be protected against corrosion, both as a preservative before laying and as a security when laid, to enable them to be raised in case of injury. The protection of the iron or steel covering by hemp alone cannot be durable; nor, indeed, are we satisfied that any of the materials submitted for protecting the iron or steel covering would be durable if exposed to abrasion. It has been suggested that for cables in shallow water, where a solid covering is wanted, the outer covering should be sought in some hard metal not acted on by sea water—probably some alloy. We believe that a coating of tin upon steel or iron wires, with a further protection by means of hemp saturated with tar or some more durable compound, or covered with a cheap form of gutta-percha would be advisable. Cables in which the strength depends on hemp will not be able to be raised for repairs, and unless the hemp is protected will be subject to destruction by marine animals and vegetation, by decay, and by abrasion on hard surfaces. The durability of hemp, however, may be much increased by coating it with some compound of gutta-percha or with marine glue. Whatever, however, be the outer covering, it should prevent any strain being brought on the inner core; the specific gravity should, therefore, be adapted to the depth, and be such as to ensure the cable sinking evenly. We understand that the specific gravity of the Toulon and Algiers cable (1·9), recently submerged in depths of from 1,600 to 2,000 fathoms, has proved satisfactory in practice.

It is also to be observed that the necessity for joints to be made in a cable whilst laying and after it is laid down is sure to occur, and must be provided for. The difficulty of making a joint even in gutta-percha wire has already been alluded to, and whatever be the outer covering, it is evident that it will often be found necessary to make joints in it at sea under circumstances of considerable difficulty. In the ordinary twisted cable a splice can be made almost as secure as the original cable. Longitudinally-covered cables will necessarily present greater difficulties, and the fact that joints will have to be made must be borne in mind in the selection of the outer covering of a cable. When three or four wires are included in the same covering, a defect in any one of the wires renders it necessary to cut the entire cable, and this difficulty is no doubt an objection to this kind of cable.

MEETING OF THE BRITISH ASSOCIATION AT BATH.

We publish brief abstracts of two papers read at the Bath meeting of the British Association, which will be perused with interest by all persons engaged in telegraphic pursuits:—

"On the Retardation of Electrical Signals on Land-lines," by Mr. Fleeming Jenkin.—The retardation of electrical signals through submarine cables has been studied closely for some years; but on land-lines, owing to the difficulty of the experiment, and small influence of the retardation on the signals usually employed, little attention has been paid to the phenomenon. The invention of automatic instruments, such as Professor Wheatstone's transmitting signals, which succeed one another with great rapidity, now renders the retardation an important element of calculation, even on the common aërial lines. The electric current is never received at a distant station at the very instant of its transmission; it arrives gradually, as represented in the annexed curve, in which the horizontal ordinates represent the times



after the circuit has been completed in terms of a quantity a; while the vertical ordinates represent the relative strengths of the current at each moment: thus, on any circuit the received current will have reached about 65 per cent. of its whole strength after a period of $6a$. The quantity a varies with the circumstances of each case, and is equal to $\frac{kcl^2}{\pi^2}\log_e\left(\frac{4}{3}\right)$, where k = the resistance of the conducting wire per unit of length, in electrostatic absolute measure; c the capacity per unit of length in the same measure; and l the total length of the wire; k is known for all the ordinary metals, but c has hitherto been undetermined; and the object of the paper was to deduce the value of c from some experiments made by M. Guillemin, and fully detailed in the "Annales de Physique et de Chimie" for 1860. These experiments gave with considerable accuracy the form of the curve for various lengths; but the experimenter had not applied his results so as to give the constants required for the mathematical theory. After describing the method employed by M. Guillemin with high commendation, Mr. Jenkin gave the results of his calculations. The electro-statical capacity per foot of the common No. 8 wire in the lines used by M. Guillemin must have been from 0·15 to 0·22 in British absolute electro-static measure (feet, grains, seconds). This number is nearly three times that given by pure theory for a wire stretched horizontally, without supports, at a uniform height of ten feet from the ground, a discrepancy probably to be accounted for by the induction occurring at each post. The form of the curve was also modified by imperfect insulation. The retardation due to this statical charge—the capacity for which is thus determined—not only delays the signals, but causes confusion and utter illegibility if they succeed each other too rapidly. A limit is thus put to the performance of signalling instruments; and calculations made with the above value of c show that we must not expect to transmit by the common Morse instrument more than about twenty words per minute between stations 1,300 miles apart; that the performance of Professor Wheatstone's beautiful automatic transmitter may be limited to speeds below 120 words per minute when 530 miles are exceeded; and that the Chevalier Bonelli would have to diminish his speed of 400 wo ds per minute (with five wires), even on considerably shorter circuits. It must be remembered that larger wires, fewer posts, and a better form of insulator may considerably extend these limits.

"On Balata and other Gums regarded as a Substitute for Gutta-percha," by Dr. R. Riddell.—The paper spoke of the gum as a very excellent substitute for, and quite equal to, the adulterated or reboiled gutta-percha from Singapore. They were indebted to Dr. Van Holst, of Amsterdam, Berbice, for bringing this gum first into notice in 1860. It abounded in the forests of British Guiana, and was especially prolific at the time of the full moon. On the day of the full moon the yield of gum was from six to ten times greater than at other times. After the tree had been tapped it could be tapped again every two months. The wood was used for building purposes and for furniture, and he was informed the tree was not injured by being tapped. A tree yielding a gum similar in every respect was discovered to exist by General Cullen and Colonel Cotton in 1853 growing along the whole line of the Western Ghauts on the Malabar coast, Southern India, from lat. 8° 30′ to lat. 10° 30′, at an elevation of from 2,500 to 3,000 feet above the sea. The climate of the country where the bullet-tree is found in Berbice is unhealthy; but however that may be, probably some of the free slaves of America might be induced to settle there and become traders. The Rev. A. M. Norman, alluding to the fact mentioned by Dr. Riddell of the sap flowing more freely at the time of the full moon, said some people were inclined to laugh at such statements, but there could be no doubt that the moon had an important influence on the vegetable world. Dr. Riddell said it was well known to the natives of India that bamboo cut at the full moon was much more subject to the attacks of insects, rotted and decayed sooner than when cut during the dark nights. Specimens of the gum in a liquid state, also in a large block and rolled, were exhibited, appearing freely coloured, but not very agreeable in smell. Other specimens were shown in a manufactured state as vulcanized, hard and soft, and in a state of ebonite. Since the Exhibition a patent has been taken out for working it, particularly for the insulation of electric wires, combined with caoutchouc and various other substances.

THE MECHANICAL PROPERTIES OF THE ATLANTIC TELEGRAPH CABLE.

There may be a trite and even vulgar sound in the popular injunction not to put too many eggs in one basket; but we think that this proverbial expression gives a reason for the success of several noted engineering arrangements, while it, at the same time, no less accounts for the failure of as many others. If a given mechanical apparatus, intended to produce a given effect, be subdivided into a greater or less number of smaller apparatuses, each subdivision being independent in its action from the others—should one of the whole number be injured, the sum total of effects is only fractionally influenced. If one or more of the tubes in a multitubular boiler happen to leak, the boiler, as a whole, is only affected to an amount roughly given by taking the proportion of the number of tubes that leak to the number that remain sound. If the leaking tubes be plugged up, the diminution in the working power of the boiler only extends to a fractional amount of its steam-producing powers. The cellular build of iron ships performs a similar function; one cell filled with water only brings the ship down lower to a determinate amount. A certain very successful valve for large mining pumps, consisting of a large number of smaller valves, cannot, even after working for a long time, give way so suddenly as the ordinary clack. The value of driving workshops with a number of engines and boilers instead of a single cumbrous engine is well-known, and part of the merit is doubtless due to the fact that all the motive power of the works cannot be stopped by the failure of a single apparatus. The same principle may be recognised in the cellular texture of the lungs and of the skin, the organs of respiration—the most indispensable vital function—a cessation of which puts an end to human life in a couple of minutes. Now it is just the fact of being dependent on a single link that makes a chain so insecure. With a chain, all the eggs are in one basket—the failure of a single link brings down the whole number. The efficiency of a chain is, however, only dependent on mechanical conditions. In the case of a submarine telegraph cable its efficiency depends on a number of physical conditions, besides the absolute mechanical condition of there being no mechanical breach of continuity. The conducting power of a submarine telegraphic cable immersed in water would be affected by an opening much less than one-sixteenth wide. In this way we may say that, practically, the Atlantic telegraph cable, 2,200 miles long, is as a chain of that length, with links (say) one-sixteenth long, while the failure of any one of which links would result in the failure of the 2,200 miles long cable. We think that this consideration roughly explains the fact that, out of the 11,000 miles of cable which have been laid since 1840, but a little more than a quarter of this total length is now in working condition.

The counter observations which might be made, "that it is unfair to take the whole number of miles which had been rejected for a few faults," is scarcely logical; or is, at least, only in so far true as it might be applied to a chain cable which, otherwise good, had caused the loss of the ship through a defect in a single link. Calmly considered, and looking at all the difficulties to be encountered in submarine telegraphy, nothing bolder can be thought of than conducting a mysterious fluid through a slender rope thousands of miles long, and laid down in depths never beheld by human eye. Upon the whole, we should say that a good deal of this boldness has been the boldness of want of knowledge and experience. We do not say this because of the many failures that have taken place in submarine telegraphy, but because there is still so much diversity of opinion on many very important points connected with the business, and because so many experi-

ments are still necessary. No doubt the numerous failures may be looked upon as experiments, but these experiments have been rather costly. Perhaps the Atlantic telegraph cable might be considered a very useful experiment, but experiments with the Atlantic for a laboratory must give results somewhat out of proportion in usefulness to expense.

In this engineering case, as in so many others for the last generation, Mr. Fairbairn's invaluable assistance has been secured in making the experiments that will, it is hoped, lead to the next Atlantic cable being itself something better than a gigantic experiment. We should say that if Mr. Fairbairn's assistance had been called upon earlier and to a greater extent before 1858, and if, in fact, an undertaking fraught with such enormous difficulties had been carefully prepared by previous experiment, at least the question whether an Atlantic cable be practicable or not would have been settled by this time. Mr. Fairbairn gave an interesting account of the work he is now conducting for the directors of the Atlantic Cable Company before the British Association at Bath, and he has also contributed a very valuable paper on the subject to our contemporary, the *Quarterly Journal of Science*. He has confined himself more especially to the mechanical properties of the Atlantic cable, and we will strive to briefly follow him in this single direction, one amongst the numerous others from which may be regarded the apparently simple, yet in reality extremely complicated, problem of submarine telegraphy.

Mr. Fairbairn observes that "in deep-sea lines there are three points which require careful consideration, and which appear essential to success, namely, the tensile strength and conducting power of the cable, perfect insulation, and machinery calculated to pass the cable with safety from the ship into the sea." He quotes the table from the commissioners' report, showing the remarkable diminution of the conducting power of copper through being alloyed. For instance, the conducting power of pure copper being taken at 100, that of Spanish Rio Tinto copper is only 14·24. At the time the experiments were made by the commissioners, the remarkable effect of alloying phosphorus to copper—analogous in its effects to carbon on iron—was not generally known. Unfortunately, however, according to Mr. C. W. Siemens, the conducting power of phosphuretted copper is found to be reduced to about one-fifth of what it was before the phosphorus was added. The relative advantages and disadvantages of gutta-percha and caoutchouc, when used for the insulation of submarine telegraph wires, are still a matter of debate amongst telegraphic engineers. Mr. Fairbairn has made a large number of experiments upon the effect of temperature and hydrostatic pressure on both gutta-percha and caoutchouc, and he states that "the general results appear to be that temperature has a very marked effect upon gutta-percha, but that pressure appears to consolidate the material and improve the insulation of both gutta-percha and india-rubber." Few substances are less understood than these extraordinary vegetable gums. Mr. Fairbairn has published, *in extenso*, his experiments intended to determine the value of the different kinds of insulators under severe pressure, and the amount of water they absorbed under hydraulic pressures equivalent to those of the known depths of the Atlantic, and under the combined influence of temperature. He found that the absorption increases "the longer the specimen is retained under water, the greater the pressure to which it is subjected, and the higher the temperature of the water in which it is immersed." The least permeable material was Chatterton's compound, the most was unmasticated bottle india-rubber. The hydraulic pressure was produced in the specimens by immersing them in a steel cylinder containing water, and fitted with a plunger weighted down by a loaded lever. The order of merit in resisting absorption was:—1, vulcanised india-rubber; 2, Chatterton's compound; 3, gutta-percha; 4, masticated india-rubber; 5, Wray's compound; 6, carbonised india-rubber; 7, india-rubber not masticated. The pressure first employed was 5,900 lb. per square inch, but when this pressure was raised to 15,000 lb., Chatterton's compound took the first rank, and gutta-percha the next. In order to test the effect of temperature the steel cylinder was immersed in a water-bath, heated with a gas flame. It was then found that temperature has a very considerable effect on the amount of water absorbed. "Thus gutta-percha, at 45 degrees, absorbed 0·044 grains; at 75 degrees, 0·27 grains, or six times as much. In like manner, india-rubber absorbed 0·177 grains at a lower temperature, and 0·45 at the higher, or two-and-a-half times as much." In order to determine the insulating power of the different cores under pressure, Mr. Fairbairn found it necessary to employ frictional electricity, conducted through a core placed in a steel cylinder, with the ends projecting. At either end of the cylinder were two brass glands, in order to tighten round the core to be tested a vulcanised india-rubber packing. A small cylinder, communicating at right angles with the larger one, was fitted with a solid plunger, to which the pressure on the water was applied by means of a lever. The water, at pressures above 10,000 lbs., appears to have forced its way out; and it is possible that the use of a self-adjusting packing, like that on hydraulic presses, might have prevented this. A summary of results is given, showing approximately the time required in each kind of core for a loss of charge equivalent to a fall of the electrometer needle of 50 degrees. These results are of a very anomalous character. For instance, No. 1, the Gibraltar core, cased by Mackintosh, showed a power of retention of 136 minutes, after an immersion of 282 hours, and under the enormous pressure of 10,000 lbs. per square inch. "At 325 hours' immersion it is reduced to 100 min.; and at 405 hours' it is still further reduced to 32 min., showing that the insulation is very considerably affected when a sufficiently long period of time is allowed for the permeation of the cable." The insulation of No. 6, a core of pure india-rubber, was almost entirely destroyed after an immersion of eighty hours. Mr. Fairbairn says that "the very important question of insulation in deeply-submerged cables is far from having received, as yet, a complete solution. The foregoing experiments are satisfactory, in so far as they show, approximately, the relative porosity of various materials; but they do not point out how we are to obtain an insulator impermeable to water, and at the same time a good non-conductor." Mr. Fairbairn states that a second series of elaborate experiments has been instituted under the direction of a scientific committee. From the drawings and figures given in Mr. Fairbairn's paper, it appears that the Atlantic cable of 1864-5 differs in several important respects from that of 1858. The conductor is a copper strand of seven wires (six laid round one), weighing 300 lb. per nautical mile. These wires are embedded in Chatterton's compound (consisting of gutta-percha and resinous substances). The wires are of the ordinary 18-gauge, and the strand of the No. 10 gauge. The insulation consists of gutta-percha and of Chatterton's compound—four layers of the gutta-percha being laid on alternately with four thin layers of Chatterton's compound. The weight of the entire material forming the insulation is 400 lb. per nautical mile. The diameter of the core is 0·464; its circumference, 1·392. The external protection consists of ten solid No. 13-guage wires, drawn from Webster and Horsfall's homogeneous iron, each wire surrounded separately with five strands of Manilla yarn, "saturated with a preservative compound, and the whole laid spirally round the core," which is itself padded with ordinary hemp, saturated with a preservative mixture. The weight in air is 35 cwt. 3 qrs. per nautical mile. The weight in water is 14 cwt. per nautical mile, or equal to eleven times its weight in water per knot. Its breaking strength is 7 tons 15 cwt., and it will thus bear its own weight in eleven miles depth of water; the contract strain is thus equal to eleven times its own weight per nautical mile in water. The 1864-5 cable is only about 4 cwt. less than double the weight of that of 1858, while its breaking strength is more than double. We should like to know its amount of resilience, or the percentage of elongation it could take without a permanent set. This would give some measure of the amount of injury to which the cable would be liable when paying it out. It would also be interesting to know what portion, whether the core or the outside protection, would first take a permanent set, leading to ultimate rupture. Doubtless this would first take place with the core, and is already only too well known, and has, indeed, been publicly stated by Mr. Fleeming Jenkin, that in nine cases out of ten a failure is accompanied by a break in the copper conductor. In our number for August 26th, referring to wire rope, we pointed out that "the tension on a wire rope merely increases the pitch of the spirals, while the core undergoes a longitudinal strain." This observation was, at the meeting last month of the British Association, at Bath, applied by Captain Selwyn, to telegraph cables. He urged that the first strain on an ordinary cable must be borne by the straight conducting wire. He advised the use of straight wires all through. But this, again, would be objectionable, as only the wires on the outside of the bundle of parallel wires would stretch, when wound on a drum, and it is just these wires that would be stretched in excess of the limit of elasticity. We notice an observation of Mr. Fairbairn, which, coming from such a source, is rather ominously significant. He says, referring to insulators generally, and more especially to the effect of great hydraulic pressure acting through a length of time:—"To solve these questions we require, in my opinion, a long series of carefully-conducted experiments, which would tend to give a reliability to these important undertakings, *which at present they have not attained.*"—*Engineeer.*

THE ANGLO-AUSTRALIAN TELEGRAPH.

Since the date of our last issue the following correspondence has appeared in the columns of the *Times* on the above subject:—

Sir,—Owing to my absence from town, I have only just seen the letter signed "C," in your impression of the 12th instant, in which the writer disputes the practicability of carrying a line of telegraph by way of Singapore to China and Australia, and charges me with an over-developed imagination for venturing to treat of such an enterprise as a work not only possible, but actually to be realized within a short time. Your correspondent commences by asserting that the length of the proposed system between Rangoon and Singapore will be laid for the most part on a coral bottom, while in reality the track laid down for the proposed line passes over regular soundings of sand, shells, and ooze, except near the different landing-places, where the usual massive shore cables will be laid, similar to those successfully used for many years under similar circumstances. Taking the next section, between Singapore and Hong Kong, your correspondent further states that the line must be laid in very considerable depths, while the fact is that the contemplated route by way of Saigon passes over an even and favourable bottom with depths not exceeding fifty fathoms, at which a submarine cable can be repaired without difficulty, or be picked up and laid down again at pleasure. Between Singapore and Batavia the line will be partly submarine, and partly by land through the island of Banca, the former being laid on an even bottom. The water in this section is somewhat shallower than would be selected as a matter of choice, but not more so than is the case with the various cables

crossing the North Sea and English Channel, connecting this country with Denmark, Hanover, Holland, Belgium, and France. It is true that these cables are sometimes injured, but they are speedily restored to working order. From Java your correspondent lays out a route direct from Batavia, being probably unaware that a land line has been in operation for a long time throughout the island. Between Java and Timor soundings have not yet been taken by way of Coupang; but there is no reason to doubt that a suitable route can be laid down. If, however, this should not be accomplished, the cable can be submerged from Madura to Macassar over soundings, and thence to Delli, the Portuguese settlement on the north coast of Timor. Between Timor and the Australian coast the water is shallow, except for about seventy miles south of Timor. On the Australian coast "C" selects Cape York as the landing-place for the cable, and says that a land wire will have to be carried 2,500 miles from that point to Brisbane, Sydney, Melbourne, and Adelaide, to complete the entire undertaking alluded to in my former letter. Even this section is not without its dangers, for his fertile imagination conjures up savages and their squaws to carry off the wire piecemeal. It is fortunate that the greater part of this length is already at work, all the cities enumerated being connected with each other at the present time. The Queensland Legislature have also voted the supplies for erecting the wire from Brisbane to Port Denison, leaving some 500 miles only to complete the communication with the head of the Gulf of Carpentaria (to which point the cable will be extended from Timor with two intermediate stations—one at Port Essington, the other at Wessel Island), and this length the Government of Queensland have undertaken to make when measures are further matured for laying the cable. These few details will show that the idea of telegraphic communication with Australia is not chimerical as your correspondent appears to suppose; and I would venture to remind him that thirteen years since the proposition for connecting England and France by telegraph was equally regarded as a poetic illusion.—I have the honour to be, Sir, your most obedient servant,

1, Victoria-street, Westminster, Oct. 15. CHARLES T. BRIGHT.

Sir,—Sir Charles Bright has made a show of replying to my letter, but he has not answered it. He begins by saying that for the 1,000 miles which lie between Rangoon and Singapore his submarine cable is to lie in soft ooze, except at the landing-places. How can that possibly be, when from the very necessities of the locality it must run through many places for half its course abounding in the coral reefs which are of the nature of these latitudes? The Indian Government had a cable made to connect the two places in question, but, discovering their mistake, abandoned the project. That very cable now connects Malta and Alexandria, and, although lying in soft ooze, has been repeatedly broken. As to the route between Singapore and Hong Kong your correspondent says that the utmost depth of the China Seas is not above fifty fathoms—a depth at which a cable "may be picked up and laid down again at pleasure." What! no difficulty in doing this, when for a great part of the year half a gale of wind blows persistently from one quarter, with the occasional interlude of a typhoon? Sir Charles Bright's cable is, I now find, to have a resting station at Saigon. This will take it full 200 miles out of the straight course, and consequently the total length of this branch will be not 1,500 miles, as I stated, but 1,700. For the first 350 miles it must pass through or along islands with the same coral reefs which so often broke the Dutch cable to the west of the Malay Peninsula. As to the cable between Singapore and Batavia, all that Sir Charles Bright says about it is that it is "to be laid on an even bottom," a quality of bottom which he alone has discovered, but how or where he says not. Sir Charles's submarine cable is, according to his statement, to be reduced by a land wire to pass through Banca. Now, the length of this island is 120 miles, and so the submarine line will be no more than 530 miles. Of the repeated rupture of the Dutch cable, and its ultimate abandonment, the engineer maintains a prudent silence. We come next to the cable to be laid from Batavia, and which, passing through the Straits of Sunda, I made to land at Cape York, the whole distance being about 2,500 miles. From this distance Sir Charles Bright very properly deducts the land wire passing through Java, so that the distance which I gave for a submarine cable in this direction would be reduced to 1,900 miles. Sir Charles, however, seems now to give a preference to a new route, which is to begin with Java or the adjacent island of Madura, and proceed by Macassar, in the island of Celebes, and the Portuguese settlement of Delli, in the island of Timor, and at the head of the Gulf of Carpentaria. The object of this route is to avoid a sea of impracticable depth. From Java or Madura to Macassar the distance is about 600 miles, and from Macassar to Timor it is not less than 780. In the first stage of this route the sea is not shallow enough for an electric cable, but in the last it is sometimes shallow enough; in others, towards Timor, of great depth, and always unequal, with abundance of the coral formation which is inseparable from these latitudes. From Timor to the head of the Gulf of Carpentaria, making Port Essington and Wessel Islands intermediate stations, the distance seems to be about 1,260 miles, making the total submarine cable 2,640 miles, or 140 miles longer than I made it from Batavia to Cape York. It might, indeed, be shortened by a wire across Timor, but this would reduce its length by no more than fifty miles, and the attempt might not be worth making, since most of the country to be passed through is in the possession of wild and mischievous tribes, who owe no allegiance to the Portuguese. Sir Charles Bright tells us that there are but seventy miles of very deep waters, but from whom he has obtained this consolatory information he does not say. The distance from Timor to Port Essington is from 700 to 800 miles, and, I understand, almost every foot of it is water so deep that it has never been fathomed, and which, for what any one knows to the contrary, may be unfathomable. This broad and deep sea, distinguished from the comparatively shallow one to the north of it, forms the line of demarcation which separates two great geographical provinces of the earth's surface from each other, remarkable for the discordance of their vegetable and animal productions, man himself included. Sir Charles Bright says that a telegraphic land communication is already established from Adelaide to Brisbane. By all means, therefore, let them be struck off the work to be done. Still there will remain the land wire from Brisbane to the head of the Gulf of Carpentaria, a distance of not less than 1,000 miles over a desert inhabited by roving savages, with nothing to eat beyond a chance kangaroo. As to the submarine line, the extent of cable which Sir Charles Bright proposes to lay down in three short years' time amounts to 3,878 miles, or but 130 miles short of the breadth of the Atlantic thrice told! Sir Charles Bright reminds me that the scheme for connecting England and France by telegraph was thirteen years ago considered as chimerical as I now consider a connection of the same kind between England and Australia. On my part, I must beg him to consider the difference as to facility of accomplishment of a cable twenty-one miles long, and one which, passing by India, cannot be less than 10,000 long. He admits that the cables which cross the narrow seas of Europe are "sometimes injured, but speedily restored to working order." No doubt they are easily repaired, but only because they are very short; and all the means and appliances, the material, and the skill close at hand. What can there be in common between such a case and an electric wire which extends to the Antipodes, and passes along the shores of barbarians and over wide seas which are seldom visited by the canoe of a savage?

October 17. C.

Sir,—The key to the difference of opinion between your correspondent "C" and myself, as to the feasibility of extending a line of telegraph from India to Australia and China may be found in the following paragraph in his last letter, referring to the depth of water between Timor and Port Essington:—"Sir Charles Bright tells us that there are but 70 miles of very deep waters, but from whom he has obtained this consolatory information he does not say. The distance from Timor to Port Essington is from 700 to 800 miles, and I understand almost every foot of it is water so deep that it has never been fathomed, and which, for what any one knows, may be unfathomable." Upon this foundation a theory is built up that this "broad and deep sea" indicates the point of separation between two great portions of the earth and its inhabitants. Your correspondent will find the information he seeks in the Admiralty chart of the northern portion of Australia and the adjacent islands, published in March, 1862. He will there perceive that the whole of the sea between the Australian coast and Timor, with the exception of a portion varying from 40 to 90 miles from the island, is under 80 fathoms in depth, the greater part varying from 30 to 50 fathoms. The proposed cable between Timor and Port Essington would, as I stated before, be laid in this comparatively shallow depth, with the exception of about 70 miles of its length, as to which we have no information; but there is no reason to anticipate very deep water, nor did I express any such belief. The same chart will acquaint your correspondent that the distance between Port Essington and the furthest point of Timor is 500 miles, the nearest point being 330 miles. It is scarcely fair that "C" should occupy your space and my time in correcting these mistakes when the information can be so readily acquired from the most obvious sources. In his former letter your correspondent asserted that the water between Hong Kong and Singapore was of "very considerable depth." In his letter published to-day he does not dispute the accuracy of my counter-statement, that the depth is not more than 50 fathoms. He states, however, in reference to the section between Madura and Macassar, to which I referred as forming part of an alternative route between Java and Timor, that the depth is not shallow enough for an electric cable, and he gives the distance as 600 miles. I can only refer him to the English and Dutch charts, from which he will see that the depths in this section average 40 fathoms, which I consider a very suitable depth for a cable. The exact distance in a direct line is 330 miles, but this would probably be increased in laying the cable to 360 miles, in order to take the best course. Your correspondent again states that the Rangoon and Singapore line must be partly laid on coral. I repeat that although coral does exist in the sea proposed to be traversed, yet that the cable can be laid altogether clear of it, and that in the actual track laid out the whole of the route is over a favourable bottom. The destination of the present Malta and Alexandria cable was abandoned, not on account of any supposed difficulties between Rangoon and Singapore, but in consequence of one of the cable ships running ashore at Plymouth on her way out to Singapore; this caused the loss of the favourable season for laying, and rendered it necessary to change the destination of the cable, as it was unadvisable to incur the risk and expense of keeping it on board the vessels for another season. Your correspondent refers again to the cable laid by the Dutch Government in 1859 between Singapore and Batavia. This was one of the earliest long submarine lines laid, and was altogether too slight. The outer iron covering was soon destroyed by the chemical action of the salt water, and the naked core was so frequently broken by anchors and currents that it was not worth repairing. It was laid, contrary to the advice of the contractor, between Sumatra and Banco, where the water is very shallow and

where strong currents prevail. The cables which are now proposed to be laid will be very much stronger, and different in many respects from those originally designed for long submarine lines. In reference to the Australian land-line between Brisbane and the head of the Gulf of Carpentaria, which "C" supposes will cross a desert, I may state that the intervening country is now settled to within 100 miles of the head of the Gulf. The Government of Queensland has undertaken to construct this portion of the telegraph, and it may be assumed they have good reason to be satisfied as to its practicability. Your correspondent, referring to the commencement of submarine telegraphy, begs me to consider the difference between laying a short cable in the English Channel and a long one in Eastern seas, and remarks upon the difference between repairing a cable crossing the narrow seas of Europe and the same operation in the parts under discussion. I look upon the connection of England with France by submarine telegraph, considering the state of our knowledge at the time, to have been a more difficult achievement then than the carrying out of the contemplated lines now, and so far as length is concerned the longest proposed section will be shorter than one of the sections of the Malta and Alexandria line, while most of them are not longer than the cable connecting this country with Denmark. With two steamers fitted with the necessary appliances for repairing cables (such as the steamer stationed on the Persian Gulf line), and a store of spare cable at the various stations, there would be no difficulty in maintaining the whole of the proposed lines in efficient and permanent working order.—I have the honour to be, Sir, your most obedient servant,

1, Victoria-street, Westminster, Oct. 18. CHARLES T. BRIGHT.

Sir,—I observe that in "C's" letter, which appears in the *Times* of this morning, he states, with reference to the Rangoon Singapore cable, that the Indian Government had a cable made to "connect the two places in question, but discovering their mistake, abandoned the project. That very cable now connects Malta and Alexandria, and although lying in soft ooze has been repeatedly broken." Now, Sir, as I was engineer to the Government for the cable in question, I am in a position to state that "C" is altogether wrong in the reason he assigns for the change in the destination of the cable. The steamship Victoria sailed for Singapore with a portion of the cable on board in December, 1860, but was met by a violent storm in the Channel, and had to put into Plymouth. This vessel was wrecked in entering the inner harbour. The delay thus occasioned caused the loss of the favourable season for laying a cable between Rangoon and Singapore, and Her Majesty's Government decided to change its destination, and to lay it between Malta and Alexandria rather than incur the expense and the risk of keeping it for several months on board the vessels. The termination of the China war about that time no doubt caused the change in the destination to be less regretted. In my opinion, the depth and nature of the sea bottom between Rangoon and Singapore are more favourable for laying and maintaining a cable than between Malta and Alexandria. It will throw light on the discussion with reference to the India, Australia, and China telegraph if I take this opportunity of shortly stating the results of over three years' experience of the working of the Malta and Alexandria telegraph, which is the first long submarine line which has proved permanently successful. The total length of cable laid between Malta and Alexandria is 1,330 knots, equal to about 1,550 statute miles. This cable was completed on the 23rd of September, 1861, and has, therefore, been submerged more than three years. The first two sections—viz., Malta to Tripoli and Tripoli to Benghazi, a total length of 860 statute miles, which have been laid three years and five months, have never for one moment ceased to work, or given the slightest cause for anxiety, but test at present as well as when first laid. The Malta-Tripoli section has a *maximum*, *minimum*, and mean depth of 420, 50, and 133 fathoms respectively. That of the Tripoli-Benghazi section 150, 25, and 71 fathoms respectively. I regret I cannot speak so favourably of the last section—viz., that from Benghazi to Alexandria, representing a length of cable of 692 statute miles. The sea bottom over this section is much the most unfavourable of the three sections for a submarine cable, having, as the charts will show, a most irregular and uneven bottom, in places very rocky and exposed. At the time this cable was laid it was, moreover, very imperfectly surveyed, although Captain Spratt did his utmost during the short time allowed him to give us proper surveys. As engineer to the Government, I desired to have the cable laid over a uniform bottom of about 50 fathoms, but principally owing to the unavoidable absence of sufficiently detailed soundings this result was not attained on the section between Benghazi and Alexandria. This portion of the cable lies in the following depths—viz., *maximum*, 115 fathoms; *minimum*, 13 fathoms; mean, 47 fathoms. This section has been subjected to three casualties, all occurring in very shallow water, where the cable lies, not as is described by "C" in "soft ooze," but on a hard, rough, and rocky bottom. These casualties occurred as follows:—June 16, 1863, repaired August 10, 1863—55 days out of working order; January 16, 1864, repaired March 19, 1864—62 days out of working order; September 5, 1864, repaired September 26, 1864—20 days out of working order; total, 137 days out of working order in over three years. Had a steamer been at hand ready and available for repairs there is no reason why the total duration of the above interruptions should not have been reduced to about 30 days. In conclusion, I may remark that the Malta and Alexandria cable is much lighter than the cable proposed to be laid in the India and China Seas, and has no external protection to protect the outside wires from corrosion. I leave Sir C. Bright to deal with the other portion of "C's" letters, in which I feel he will have no difficulty, as "C" is evidently writing without having examined the very detailed charts of the seas in question. Apologising for the length of this letter, I remain, your obedient servant,

6, Duke-street, Adelphi, Oct. 18. HENRY C. FORDE.

LAW INTELLIGENCE.

BOVILL *v.* BONELLI'S ELECTRIC TELEGRAPH COMPANY. AGRA AND UNITED SERVICE BANK, GARNISHEES.

On Monday, the 17th instant, in the Lord Mayor's Court, this attachment case was brought before the Recorder and a common jury, in which the plaintiff sought to recover £1,376, moneys in the hands of the garnishees, to the credit of the defendants.

Mr. Mathew, for the plaintiff, said that the defendants were indebted to his client in and above the sum now sought to be recovered. As there was no defence to the present proceedings, the only question for the jury was whether a certain sum of money was in the hands of the garnishees.

Mr. Danby said: I am a clerk in the Agra and United Service Bank. On June 20th Bonelli's Electric Telegraph Company had a deposit account at the bank. The balance on June 30th was £1,376.

As no one appeared for the defendants, his lordship directed the jury to return a verdict for the plaintiff.

Verdict for the plaintiff accordingly.

CORRESPONDENCE.

THE NEW ATLANTIC CABLE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Your correspondent "Progress" has called the attention of your readers to a most important matter relating to the future of deep-sea telegraphy. We all admit the great abilities and experience of Dr. Fairbairn as a civil engineer, but his knowledge of electricity and hempen ropes cannot be very extensive, if we may judge from the paper read before the British Association at Bath, nor, in fact, has Dr. Fairbairn full confidence in the design adopted for the Atlantic cable which he has, nevertheless, recommended after subjecting it to a series of tests at his works at Manchester. It is a great pity that some of those gentlemen who have had practical experience in the manipulation of ropes, and in the submersion of deep-sea cables, were not consulted upon the subject before arriving at a final decision. I believe that the core is constructed upon approved principles, and if successfully submerged will answer the full expectation of its designers. J. MARLOW.

RAILWAY ACCIDENTS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—The importance of the above subject becomes daily more and more urgent, as accident after accident occurs on our lines to the terror of the travelling public. We have had in the space of a few weeks several accidents involving the loss of life and the destruction of property, which it is admitted might have been avoided had an efficient system of signals been in use. I have noticed on several of the lines that the mechanical system of semaphores employed was allowed to remain in a most unsatisfactory condition with respect to the wires conveyed on pullies along the line, the wires in several instances being almost entirely destroyed by rust, or the wheels or pullies allowed to fall down, so as to be of no use in the working of the signals. I believe that on several lines where electric signals are employed too little care is taken to keep the conducting wires in a good state of insulation, which renders the system uncertain in its action, and has been the cause of numerous and serious accidents from time to time. Moreover, it is my opinion that we really do not yet possess an efficient and reliable system of electric signals on any of our lines, and even their diversity is an evil. You have promised a description of Mr. Preece's semaphore system, which, I believe, has been adopted on some of our principal lines; but as I have not read an account of the construction thereof, I am not in a position to pass any opinion as to its merits.—Your obedient servant,

20th October, 1864. A TRAVELLER.

MAGNETIC NEEDLE THREADER.—Magnetism has been applied to a great many useful purposes, with more or less success. The most recent invention in which this agent has been applied is a needle threader, patented in America June 14, 1864, by Oliver Cox, of Washington, and since assigned to Munson, Cox & Lemon, of that city. This threader consists of a small piece of steel, having a straight groove on one side for the reception of the needle, and a taper hole opposite to where the eye of the needle comes, to to conduct the thread into the eye. The steel is magnetized, so that the needle to be threaded is held in the groove by its attraction, without the aid of a spring. By this means the threader is made very simple, and affords much greater facility for threading a needle than the threaders with springs. It can be used for needles of various sizes, and does not get out of order.

TELEGRAPHIC NEWS.

The Telegraph in New South Wales.—A comparative statement of the revenue of this colony, during the quarters ending 30th June, 1863, and 30th June, 1864, shows that the receipts from the electric telegraph have increased £15.

South Australian Telegraphs.—The sum of £3,000 has been voted for telegraphic extension to Blanche Town, on the Murray. The New South Wales Government are about to construct an independent line of telegraph between Sydney and this colony.

Telegraphy in India.—The faulty part of the telegraph cable on the Mussendom to Gwadur section has been discovered buried in earth. The defective part has been cut away, and will be replaced by new cable, when the line will again be opened for traffic.

Atlantic Telegraph Company.—On the 20th instant a call of £1 5s. per share was made by the directors of the Atlantic Telegraph Company upon the £5 (8 per cent. preferential) shares, making £8 15s. per share paid up. A further and final call upon the preferential capital is expected in January next.

Telegraphic Communication between Malta and Alexandria.—We are glad to learn that telegraphic communication, after an interruption of about twenty days, is now re-established to Alexandria, and that the Malta and Alexandria line is again open to the public. This speedy restoration of the electric telegraph reflects great credit on the expedition.

The Russian American Telegraph Line.—The first working party connected with Capt. Bulkley's great expedition for the construction of the Russian and American telegraph line, left New York on the 24th ult., in the steamer Golden Rule, for San Francisco, via Nicaragua. The party consists of Mr. Conway, telegraph engineers, and a number of assistants, who, under the directions of Capt. Bulkley, will proceed to various points in British Columbia, to make the necessary surveys preparatory to more active operations next spring.—*The Telegrapher.*

Telegraphs in Europe.—A comparative estimate, just published, shows that the telegraphic lines in France comprise 98,446 kilometres (each five-eighths of a mile) of wire, and 1,301 offices, which transmit about a million and a-half private despatches a year, and nearly half as many official ones. Russia has 48,884 kilometres of wire; Austria, 29,640; Italy, 25,561; Prussia, 32,273; Spain, 23,665; Belgium, 6,238; Switzerland, 4,960. In Spain and France the telegraphs are under the control of the Minister of the Interior. In Russia, Prussia and Italy they belong to the Ministry of Public Works.

Private Telegraphy.—A line of telegraph has just been completed by Mr. Bartholomew, for Messrs. Hawthorn, between their engine works in Leith and Granton. Several important improvements in insulation have been introduced. The instruments differ widely in their construction from those which have hitherto been adopted in several parts of the country. The instruments generally adopted require the use of both hands, or of the feet and hand for the purpose of generating electricity and sending the message. Bartholomew's instruments, however, require the use of only one hand. Hitherto one of the chief objections to private telegraphy has been the extremely complex nature of the mechanism, which, coupled with the great number of springs, has proved a fruitful source of annoyance from the frequency of their failure. The instruments at Messrs. Hawthorn's, however, are said to be marked by an almost total absence of springs, and have even proved to be less liable to derangement than any other kind.—*Building News.*

Telegraphy in America.—On the 26th ultimo was published in New York, under the auspices of the National Telegraph Union, the first number of a new monthly, yclept *The Telegrapher.* A copy is to hand, from which we learn that it is intended to contain from time to time, "besides a review of the origin, progress, and aims of the Union, and the proceedings of each and every monthly meeting of each and every district, the orders, instructions, recommendations, and calls of the President, the quarterly reports of the Treasurer, and his detailed annual report, the proceedings (except such as are necessary to be kept secret) of each and every meeting of the Convention of delegates, the orders, bills, resolutions, and enactments in full of the Conventions, editorial matter, original articles on telegraphy, telegraphic history and progress, extracts from telegraphic works, improvements in the art, promotions, changes, and removals of telegraphers, and, in fact, to contain everything honourable and truthful pertaining to the union of telegraphy." *The Telegrapher* is edited by Mr. L. H. Smith, who appears to have spared no pains in rendering the journal worthy the art it represents. We greet our trans-Atlantic contemporary with a hearty welcome, and wish it every success.

Electric Telegraph in Queensland.—The establishment of telegraphic communication between Brisbane and Moreton Bay has been most successfully accomplished. The work was commenced on the 28th of June. The most favourable place for starting the connection between Stradbroke and Moreton Island having been decided upon, it was found that, in order to avoid the flats and sand-banks, about 1,800 yards more cable would be required here than was expected; and altogether about four miles of cable were yet to be laid. It is not intended to use any portion of the cable which remains after laying the necessary quantity between Cleveland and Dunwich, as it is not thought desirable that any splicing of the cable should take place. The landing of the necessary apparatus was found very difficult and laborious, owing to the nature of the wide beach that extends from Dunwich into the sea. It was, however, successfully accomplished. The land line from Lytton to Cleveland, and from the north to the south side of Stradbroke Island, is being rapidly completed, and it is expected that, simultaneously with the arrival and laying of the remaining portion of the cable, it will be ready for the transmission of messages. The receipts of the telegraph for the quarter ending June 30th, 1864, were £1,368 11*s.* 5*d.*; for the quarter ending 30th June, 1863, £1,151 9*s.*, showing an increase in the telegraph revenue of 1864, of £217 2*s.* 5*d.*

Communication with the Cape.—An important maritime enterprise was commenced on the 14th instant, when the Union Company's Royal Mail steamer, Athens, sailed from Plymouth for the Cape of Good Hope. It is not intended that this boat shall return in the usual course, but she will henceforth ply between the Cape and the Island of Mauritius. This inaugurates a new line, which is subsidized by the British Government. Mauritius, as is well-known, is an island in the Indian ocean, 600 miles to the east of Madagascar, at which the Australian steamers stay to coal before coming on to the Red Sea and Suez. These steamers run monthly, and by the fortnightly communication now established between Mauritius and the Cape, a new route to and from the latter is established overland through France viâ Marseilles, the Red Sea, Suez to Mauritius, thence westward by the steamer Athens, now put on, to Port Natal and Cape Town. To Natal this will be the shortest, although not the least expensive route. It is as allowing of speedy communication with our important colonial possessions at the Cape by electric telegraph, however, that this new line will be of most value. At present no news thence can reach us under thirty days, or thereabouts. Henceforth that time will be lessened by nearly one-half. An electric telegraph exists between Cape Town and Natal. From Natal to Mauritius may be estimated at a five days' voyage, and from Mauritius by the Australian mail steamer to Suez at eight or nine days. From Suez there is a telegraph direct to London, and therefore, for purposes of news, the British possessions at the Cape may be reckoned as a fortnight distance from England, instead of a month as hitherto. When the Red sea telegraph is open to Aden, which it will be very shortly, this time will be further lessened by two days. The girdle round the earth is being drawn tighter. —*Western Morning News.*

Suicide of the Manager of the West-Ham Gutta-Percha Company.—On Saturday morning, the 15th instant, Mr. Charles de Ridout, a French gentlemen, the manager of the West-Ham Gutta-Percha Company, committed suicide, under circumstances showing singular deliberation. The deceased gentlemen, aged 65, resided at Norfolk-terrace, Westbourne-grove, Notting-hill. He was married, and had two or three children. Latterly he became, it is said, involved in heavy pecuniary difficulties through some loss which he experienced, and he was at times afflicted with great depression. No apprehensions were entertained by his friends that he was about to commit suicide; but at the hour of twelve o'clock on Saturday, the report of a pistol-shot was heard proceeding from the stables at the back of the West-Ham Company's Works. The attention of a police-constable was called to the fact, and an entry was effected into the stables. The unfortunate deceased was found lying on the flooring covered with blood, which issued from a wound in the head. By his side was a pocket-pistol, which had just been discharged, and it was evident that the deceased had placed the muzzle to his head, just behind the right ear, and sent the bullet into his brain. He nevertheless did not breathe his last until half-past two o'clock. He left two letters, one addressed to the coroner, referring chiefly to his pecuniary troubles, the other to his wife, to whom he wrote in the most affectionate terms. The deceased was well-known among a large circle of business men, by whom he was highly respected. An inquest was held on the 17th instant, by Mr. Payne, coroner, at St. Bartholomew's Hospital, on the body of the unfortunate gentleman. The evidence taken was confirmatory of the facts as to the pistol-shot being heard in the stable, and the finding of the body of deceased afterwards. Mr. Edward Broughton, clerk of the Gutta-Percha Works, said he knew the deceased for three years. Witness never observed that his mind was disturbed in any way. The letters produced were in deceased's handwriting. Witness knew that he was involved in pecuniary difficulties. The accounts of the deceased with the company were perfectly correct; but it appeared that he was about to be discharged, his services not being required, as the West-Ham Gutta-Percha Company had transferred its business to the India-Rubber, Gutta-Percha, and Telegraph Works Company, and he was apparently desponding on that account. A letter addressed by the deceased to the coroner and jury was likewise read. After stating his pecuniary difficulties, he writes: "I die, believing nothing but hoping all things. I write all this, because there is always so much said about death being a rash act, a rushing into the presence of one's Maker without God's permission. I feel but an instrument in God's hand for my own just punishment. I placed all my happiness in a home to which I had no right, for I had not the means necessary to keep it up. What tricks and subterfuges in order to make this home happy! I am ashamed to make so much fuss about dying, but the thought of them overcomes me. My dying averts ruin from another, who, if I lived, would be ruined." The jury returned a verdict of "Suicide while in a state of unsound mind."

Demolition of the Great Exhibition Building.—On Monday last a number of persons visited the neighbourhood of the Great Exhibition building, it having been announced that it was intended to blow down the two towers that supported the great dome, adjacent to the Horticultural

Gardens, in the Exhibition-road, but the operation was postponed for a day or two, to enable Sir John Burgoyne and other officers of the Royal Engineers, from Chatham, to be present at the operation. The public, however, had the opportunity of witnessing the corps of Sappers and Miners, under Capt. Knocker, at work upon the basement of the towers, where they were engaged during the day in boring at intervals in the brickwork the requisite chambers for the displosion, large orifices being formed for the reception of the explosive charges, some twenty or thirty in number, representing a total undermining powder force of 100 lbs. weight to each tower. These charges are proportioned to the weight and thickness of the walls, and to the distances of the borings apart from one another; and, after the charges are put in, the holes are "tamped," and then fired by electric batteries, at a range of about 200 feet, all the charges and wires being automatically connected one with another. The height of the towers is 70 feet, by 40 feet in circumference, the thickness of the walls being six feet at the base, and an average of upwards of five cubic feet, the total weight of each tower being 15 tons.

INSULATING MATERIALS.—Mr. S. W. Silver, of Cornhill, has forwarded the following interesting communication to the *Times*:—"My dear Mr. Silver,—Intending to send a boat to-morrow to Gaboon, with my letters for the mail, I should be very sorry to miss the opportunity of writing to you, being the last I will have from the coast, for in a few days I start for the interior. Since my arrival here I have sent two cargoes to London, and I am very glad to be through with the trading part. Enclosed you will find a cheque, with many thanks. I have succeeded in collecting about 13 tons of rubber, which I sent in the Renshaw two days ago. I do not see that there is much difference with the other kind I have seen from the coast. I have sent a batch of gorillas to the British Museum, and I have also shipped a live one, which I sincerely hope will reach London safely. I had three of them alive a few days before the vessel sailed. Now I am going to work in earnest, and I can assure you that I will find but very little time to feel lonely, for it would not do for a man who has no one to converse with to have nothing to occupy his mind in a country like this; the only danger is to fall ill, for one always feels dull afterwards. Thanks to a kind Providence, I have enjoyed very good health, though I have taken a good deal of quinine since my arrival on the coast, but generally as a preventative. I hope to go a long way into the interior. The bed you had made for me is a capital thing, and I will think of you often at the end of a day's work, when I shall rest comfortably on it. Post-office arrangements are not very good here, so do not give me up as a dead man if you are a year or two without hearing from me. I can only assure you that I will often think of you, and of the many pleasant hours we have spent together. Please remember me kindly to ——, and with my best wishes, believe me, yours very sincerely, P. B. DU CHAILLU.—Fernand-vaz River, August 20, 1864."

MISCELLANEA.

ELECTRIC LIGHT.—At Lorient, during some experiments with the electric light, a signal mast was fixed at 700 yards and at 500 yards from two ships, when the signals given by flags from the summit of the mast were rendered perfectly visible on board by means of the electric light. A third experiment caused great surprise and admiration. A diver descended twenty feet under water, and by means of the light was enabled to distinguish the decimal divisions on a scale which was sent down to him, and to give proofs of it. This experiment was deemed conclusive. It is now established that an electro-magnetic machine may be permanently fixed to light large workshops, submarine works, and narrow passages into harbours. It was further observed that when the lime-light was brought to bear on the water shoals of fish were attracted to the surface by the unusual appearance, and continued to swim round the part lighted. Eels, and other fish which were at the bottom of the sea, came up to the surface.

PULFORD'S MAGNETIC PAINTS.—We were at a loss to understand the meaning of the above until, upon making enquiries, we found that the body of the paint, being iron, when dry, *i.e.*, not ground in oil, will adhere to the magnet—hence the name. At first we were under the impression that these paints were the same as the metallic oxide; but we have ascertained that the common metallic oxide has no magnetic properties, but is merely the coloured earth obtained near the iron mines, which, undergoing certain processes, is then ground up in oil. From experiments made these paints, we think, are at present unequalled. They have this superiority over the ordinary colours, that they will neither crack nor blister, being affected neither by weather nor climate. They must, therefore, be especially adapted for the tropics. Wherever paint is required we should say that magnetic paints must be decidedly superior to any hitherto used, which must be clear to the most uninitiated, that, from their very nature, give to any surface painted with them a coating of iron, and so preserve it from decay. We have heard from painters who have used them that they have this great advantage, by using this paint even continually, the painters cholic, from which they all more or less suffer, would be prevented. It has been tested upon ships' bottoms, and has been found to preserve the metal sheathing from decay, protecting it from barnacles, weeds, and other submarine matter. We are told that it is used in the French navy, Regent's Zoological, Crystal Palace, and other places of importance.—*The London Commercial Record*.

A TROUBLESOME PERSON IN CHEMISTRY.—A writer in the *North British Review* tells an amusing story, illustrative of the unwillingness to receive new truths which is characteristic of some minds. Long after Sir Humphrey Davy became famous in London circles as the "young chemist" who attracted larger audiences to his lectures at the Royal Institution than perhaps any purely scientific man had ever done before, there was a certain professor of chemistry in the college at Aberdeen who systematically passed over his discoveries. Some bolder spirits among the Doctor's colleagues at length aroused his attention to the subject; and the professor was compelled to take notice at last of Davy's great discovery of potassium. Accordingly at his next lecture he began by saying: "Gentleman—Both potash and soda are now said to be metallic oxides—the oxides, in fact, of two metals called potassium and sodium, by the discoverer of them—one Davy, in London, a verra troublesome person in chemistry."

A HINT TO EXPERIMENTALISTS.—Early in the month of March in the present year, Mr. F. H. Needham took the preliminary steps to secure a a patent for "electric telegraph cables, or wires, for submarine, subterranean, or over-ground purposes." This invention relates to the insulation of electric telegraph cables or wires without the use of gutta-percha, india-rubber, or such like materials. The patentee proposes to insulate electric telegraph wires by means of *an oxidised surface or coating, which will form a non-conducting covering*. In addition to such oxidated surface he proposes, for submarine wires, to apply thereto a deposit of saline earthy substances, similar to those contained in the sea, such deposit to be formed in combination with the oxidation, or subsequently thereto. The oxidised surface may be caused very readily by means of immersion in diluted acids, such as sulphuric, nitric, or hydro-chloric acid, and by exposure to moist air, or other well-known means; or the oxides of other metals, such as tin, lead, antimony, bismuth, or any of their alloys, may be made to adhere to the surface of the copper conducting wire oxidised or in a bright state. The patent has not been proceeded with.

ELECTRICITY IN WATER.—In a paper addressed to the Academy of Sciences, Dr. Scoutetten endeavours to show that the real activity of mineral waters is owing to their electricity. Imbued with this idea he at first attempted to discover traces of electricity in mineral springs by means of a gold-leaf electroscope, but without success. Continuing his experiments, he found the confirmation of Becquerel's theory, viz., that the earth in contact with a sheet of water manifests electricity; and also that, when the latter is impregnated with air, it takes a quantity of positive electricity, while the earth is negative. The same is the case with sea water, but all mineral springs are negative with regard to the earth. By the aid of Nobili's galvanometer, which is founded on the principle of the deviation of the needle under the influence of a galvanic current, Dr. Scoutetten found that, if a mineral water be brought into imperfect contact with common aerated water by means of a porous diaphragm, and if platinum electrodes be used, a regular pile is formed, and the galvanometer shows the mineral water to be negative, and the common one positive. Extending these experiments to the human body he found that mineral waters determine a current always passing from the water to the patient; they are therefore negative with respect to the latter, and the galvanometer in their case marks 70, 80, and as much as 90 degrees. Hence Dr. Scoutetten explains the efficacy of mineral springs by the three following propositions:—1. That mineral waters all determine phenomena of excitation owing to the electricity they devolve in contact with the human body. 2. That they exercise a therapeutic action, which varies according to the nature of the mineralising elements. 3. That they occasion a topical action which provokes eruptions of the skin.

FISHING BY ELECTRIC LIGHT.—The use of electricity, as a submarine light, is developing rapidly. In a recent number of this journal the application of the light to nautical purposes and in submarine works was referred to; its use in sea fishing is also of interest. It is well known that fish like moths, are attracted by light, and to be fascinated by it. Fishing by torch or other light has been long practised on the French as well as other coasts. The boats carry a skillet at their prow, and a blazing fire is kept by means of fir cones and resinous woods, but this is only one of the many modes in use. In 1857, Mons. J. Atonguia de França-Netto, an engineer of Dunkirk, made experiments in the Gulf of Finland, setting himself the following problem:—To obtain a light that should illuminate the water to the depth of 50 to 200 yards, and which should not be disturbed, like the boat beacons, by the movement of the waves. He made use of a submarine electric light, and in one case four men took a thousand pounds weight of the finest fish in forty minutes, or as much as twenty or thirty would have obtained in the ordinary manner. Having proved that a submarine light affected the fish in the same manner as one above the waves, the next thing was to obtain a lamp that would support the pressure, and the director of the famous glass-works of Baccara has produced for the purpose crystal globes nearly twenty inches in diameter, a centimetre, or two-fifths of an inch, in thickness, and weighing upwards of fifty pounds. Subsequent experiments, some of which were made by order of the French Government, have clearly proved that all kinds of fish are attracted by the light, and that when they have approached within a certain distance they seem powerless to quit the spot, and hover about the spot till captured or driven away. Mons. De França-Netto has invented a new kind of net, or trap, to use with the light, and both have been tried on the coast of England as well as of France. Means are being taken to apply the system on an extensive scale.

The First Printer of Strasbourg.—A correspondent in *Notes and Queries*, signing himself "John Gough Nichols," thus adverts to an attempt to suppress information as to the originator of the typographic art:—The first invention of the Art of Printing is placed in the city of Strasbourg; and until the year 1760 it was attributed to Johann Mentelin of that city, originally a *guldenschrieber*, a writer with or upon gold. Whilst there existed a literary controversy of long duration between the partisans of Strasbourg and Mentz for the local honour of the great invention, Mentelin was always named as the inventor at the former city, whilst at the latter the credit of the invention oscillated between the names of Guttenberg, Faust, and Schœffer. This was the state of the discussion in the year 1760, when Schœpfflin in his *Vindiciæ Typographicæ* appears to have accomplished a triumph rarely gained in such controversies. His arguments effected a sort of compromise satisfactory to the ambition of both cities, by fixing the reputation of Strasbourg as the cradle of typography, but recognising Mentz as the birth place of its inventor. The name of Mentelin was dropped, even by the historians of Alsace itself, by whom it had been commemorated for nearly three centuries; and now a statute of Guttenberg, erected at Strasbourg in a *place* which bears his name, asserts and maintains that he was really the man to whom the world is indebted for this most important art. The name of Mentelin is still on record as that of the first printer at Strasbourg, but with the year 1473 as the earliest date in a title-page or colophon. His advocates [I should mention that my attention has been directed to this subject by a Memoir, entitled, *Quelques Mots sur l'Origine de l'Imprimerie*, ou Résumé des opinions qui en attributent l'Invention à Jean Mentel, natif de Schlestadt; par A. Dorlan, avocat, Bibliothécaire de la ville de Schlestadt: printed at Schlestadt, 8vo, 1840. Whether any reply appeared I have not learned. The author is now deceased.] consider that he had printed for many years before, anonymously. I have not present time or means to discuss the question further: but I have been struck with the sententious and solemn terms of an epitaph said to have formerly existed in the Minster at Strasbourg, and of which I have attempted an English version. It was as follows:—

"I in this grave John Mentelin lie, at length,
I on whom God bestowed such grace and strength,
That from me first, of all men on this earth,
In Strasbourg here, Print-Writing took its birth,—
By types set, used; then moved, and ta'en apart,
And used again, I wrought this beauteous art.
By these *book-sticks* to write in print I taught,
And such fine art thereby so far I brought,
In one day now a man can print outright
All which erstwhile took a whole year to write.
An art so fruitful, as I surely know,
To the worlds end it will increase and grow.
Now't were but due, for all futurity,
To render thanks to God, and eke to me,
As without vanity may well be said;
But, for memorial to be justly paid,
What is enough? where is there means—or room?
Thus God himself provides: that for my tomb—
To prize my Printing in its true degree—
A mausoleum this vast Minster be."

The great question is, Were the assertions of this epitaph true or false? Another, nearly as important, Was it coeval, with Mentelin's death or no? If coeval, there is the greater probability of their being true. In either case, how shall any satisfactory excuse be devised for the conduct of Schœpfflin, to whose library the epitaph is said to have been transferred, and who never restored it to the Minster? (*Notices sur la ville de Strasbourg*, par M. Herrmann, doyen de la faculté de droit, tome ii. p. 413.) By what authority did he not only exalt Guttenberg, but put away the public testimony in favour of Mentelin?

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2533. W. R. Sykes, improvement in apparatus for transmitting positive and negative currents of electricity.
2536. L. J. Crossley, improvements in electric telegraphs.
2558. T. Corbett, improvements in signals or alarums for doors and windows, and for such other uses as the same are or may be applicable to.

NOTICES TO PROCEED.

1442. J. P. Williams and T. Robinson, improvements in annealing wire.
1873. W. Anderson, improved apparatus applicable to the working of moving parts of railway tracks, and of the signals connected therewith, and of other instruments required to be operated in a predetermined order.

TO CORRESPONDENTS.

P. Q.—We believe that most of our telegraph engineers are favourable to the adoption of cables of light specific gravity for deep-sea purposes.

I. Lambert.—Mr. Alexander Bain prepared the solution for the paper used in his electro-chemical receiving instruments by adding nitric acid to a solution of ferrocyanide of potassium until the colour becomes of a dark green, subsequently adding hydrochloric acid until the fluid becomes colourless. The paper immersed in this solution must be used before it becomes quite dry. The following recipe for a solution which answers the same purpose, and also preserves the paper in a moist condition, is given by M. Pouget Maissonneuve:—

Water	100 parts
Nitrate of ammonia in crystals	150 „
Ferrocyanide of potassium	5 „

Amateur.—To test the insulation of your wire connect one terminal of the battery to earth, and the other terminal to line through your galvanometer. The other extremity of the line wire is to be insulated. If any deflection of the galvanometer needle is observed it indicates the amount of leakage.

L. M. R.—The alphabet used for the single-needle instrument corresponds with that employed in working the Morse.

K.—Repeat your first question in a more intelligible form. A *mètre* is 39·37 inches, a *decimetre* 3·9 inches, a *centimètre* and a *millimètre* 0·039 inches.

A Student.—Mr. Highton, in his interesting "History of the Progress of the Electric Telegraph," gives the following accounts of experiments similar to those to which you refer:—"Various experiments have been tried in England, America, and India, with a view to ascertain whether it was possible to send telegraphic communication with naked wires, or even without any wires at all. In England, the author and his brother have tried many experiments on this subject. Naked wires have been sunk in canals for the purpose of ascertaining the mathematical law which governs the loss of power when no insulation was used. Communications were made with ease over a distance of a quarter of a mile. The result, however, of these experiments has been to prove that telegraphic communication could not be sent to any considerable distance without the employment of an insulating medium. In India, Dr. O'Shaughnessy has laid uninsulated wires across a river which is more than a mile broad for the purpose of transmitting telegraphic communications, and he has found it possible to transmit a current along an uninsulated wire of that length, and to obtain at the distant end an action sufficient to work his telegraphic instruments. No less than 250 galvanic cells were required, and even then the signals were scarcely visible. Professor Morse, in America, has tried various experiments in sending currents across rivers without intervening wires. All these experiments have, however, led to no practical result, except that they have proved that, were it necessary to transmit currents of electricity between two stations which are far distant from each other, insulation of a metallic medium is absolutely required. Beyond the proof of this fact, all these costly experiments have proved futile. The experiments themselves have, however, been of the highest value to the science of telegraphing by electricity, and many laws have been deduced therefrom" To the above may be added the experiments of Sir W. Watson, 1747, and Dr. B. Franklin at a later period. Mr. Alexander Bain conducted a series of experiments in Hyde-park in 1841-2, and Messrs. Beardmore, Piggott, Lindsay, and others, at subsequent dates.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

STATISTICS OF THE TELEGRAPH.

It occasionally happens that an inventor lives to see the offspring of his genius adopted by his countrymen, and employed to the advantage of mankind. Mr. W. F. Cooke is fortunate to be able to enjoy these privileges. Less than thirty years ago the electric telegraph was looked upon as a philosophic toy—ingenious certainly, but inapplicable to useful purposes. The representations of its inventor as to its capabilities were favourably entertained by a few enlightened men, while others readily denounced them as the productions of a disordered imagination. We have now become familiar with the telegraph; it is no longer a plaything, but is recognised in every city of importance in the world as a magnificent adaptation of the forces of nature to political, commercial, and social improvement. Annihilating time and space in its operation—facilitating diplomatic arrangements with remote potentates—enabling the merchants of the East to traffic with the traders of the West for their mutual profit—the telegraph has become the universal medium of intercommunication. Gratifying, therefore, must be a contemplation of the progress and continued advancement of so valuable an aid to civilization by the inventor, and others interested in science and art.

The statistics of the telegraph of the United Kingdom (not including private telegraphs, of which there are many in nearly all the large towns of England) are interesting, and show, not only a gradual increase in the number of lines open, but a great improvement in the amount of business transacted. Year by year has the electric cord extended—beneath our pathways, from pole to pole along our highways and railways, across our rivers, above our houses, and from coast to coast on the bed of the ocean itself, bringing into close communion the peoples of the earth, who are separated by distance, but whose interests in the preservation of peace, the extension of commerce, and the advancement of science are kindred to our own. The Government returns of the telegraph for 1863 have been printed, together with a comparative statement of its operations since the year 1861. The marked increase in the number of messages transmitted in 1863 proves at once the capabilities and importance of the telegraph service. In 1861 there were 11,528¾ miles of line open for public traffic; in 1862, 12,711½ miles; and in 1863, 13,892¾ miles, which consisted of 65,012½ miles of wire. Last year the number of stations was augmented in like proportion, and facilities were offered for the transmission of telegrams at no fewer than 1,755 stations, containing 6,196 instruments, through which about 3,400,000 messages were sent. The property and businesses of the several telegraph establishments last year may be thus briefly described:—Electric and International Telegraph Company: 8,230 miles of line, 39,042 miles of wire, and 1,022 stations. The number of messages sent by this company during 1863 has not transpired; but, calculating the proportion of increase from the two years immediately preceding, may be estimated at nearly 2,000,000. The British and Irish Magnetic Telegraph Company: 4,196¾ miles, 17,257½ miles of wire, 464 stations, 827,424 messages. South-Eastern Railway: 316 miles, 2,642½ miles of wire, 94 stations, 62,968 messages. London, Brighton, and South Coast Railway: 212 miles, 541½ miles of wire, 46 stations, 43,208 messages. London District Telegraph Company: 107 miles, 430 miles of wire, 81 stations, 247,606 messages. The United Kingdom Telegraph Company: 831 miles, 5,099 miles of wire, 48 stations, wherefrom 226,729 telegrams were sent.

In addition to the lines actually on British soil, the Submarine Telegraph Company has cables stretching to Calais, Boulogne, Dieppe, Jersey, Ostend, Hanover, and Denmark, with which the other lines are more or less all in connection, covering 887 miles, with 2,683 miles of wire. This company has upwards of 3,000 stations on the continent. The messages sent by it to and from foreign countries were, in 1861, 230,000; in 1862, 310,595; and in 1863, although the mileage was not increased, 345,784. A tabular statement of the telegraph lines in Europe, recently published, shows that France possesses a system comprising 71,034 miles of wire and 1,301 stations, which transmit about 1,500,000 private despatches annually, and nearly 175,000 official ones. Russia has 36,663 miles of wire; Austria, 22,230; Italy, 20,120; Prussia, 24,149; Spain, 17,743; Belgium, 3,773; Switzerland, 3,720. In England the telegraphs belong to joint-stock companies; in France and Spain they are under the control of the Minister of the Interior; in Russia, Prussia, and Italy they belong to the Ministry of Public Works.

The value and importance of the electric telegraph is apparent on consideration of its rapid extension throughout Europe. Next year the foregoing estimate may be supplemented by 12,000 or 16,000 miles of wire. Submarine telegraphy, which has hitherto held a very equivocal position in public estimation, is now on its trial. On the success or failure of the Persian Gulf and Atlantic telegraph cables will depend the confidence of the commercial community, whose aid in the development of the telegraph is necessary to second the skill and experience of our best engineers.

TO DETECT FAULTS IN UNDERGROUND LINES.

Contributed by R. S. Culley, Esq.

In repairing underground wires it is often necessary to find out which is which in places where they are not labelled. To do this it is usual to "put a current on" the wire which may be wanted, and prick or cut through the percha covering of each of the wires in the cable till the current is found.

All these holes must be accurately closed, and as this operation is difficult, and apt to be performed carelessly, several persons have contrived instruments for the purpose of detecting the current without removing the coating, but without practical success.

I beg leave to describe a contrivance of my own, which has been used by my linemen, and which I think any careful person may use with advantage. A light needle, about three inches long, is suspended by a thread in a somewhat heavy brass box, having a glass cover. The box is fixed to a vertical brass rod, which passes through a hole in a short three-legged stand, so as to slide up and down. The stand is placed over the bundle of wires, and the box adjusted, so that each wire can be brought in succession under the needle. To make the needle capable of being moved by a current in a single wire it is, of course, necessary to render it astatic. To effect this I use a bar magnet moveable on the brass suspending rod—a similar arrangement to that used by Professor Thomson in his reflecting galvanometer. As the needle, when nearly astatic, vibrates very slowly, it is not affected by a "working current," and it is delicate enough to pick out a wire having a resistance of thirty Varley's units.

THE CORRESPONDENCE IN THE *TIMES* ON THE ANGLO-AUSTRALIAN TELEGRAPH.

An interesting and important discussion has been lately going on relative to the practicability of establishing telegraphic communication between India, Singapore, China, and Australia by means of submarine cables. A correspondent, who signed himself "C," denied the possibility of laying and maintaining the proposed submarine cables; and the engineers, Sir C. Bright and Mr. Forde, asserted the practicability of doing so. These are the lines concerning which several blue-books have appeared, containing Mr. F. Gisborne's correspondence with the Australian, Dutch, and Her Majesty's Governments, and to carry out which a company was formed last summer. The company, however, has as yet made no public appeal for subscriptions. We (*Observer*) never read a statement of facts which more completely satisfied us that the weight of evidence is in favour of the opinion of the engineers. It is true that "C," as it turned out, had not examined the Admiralty charts, at all, or, at least, not with any sufficient care, and was, therefore, hardly a worthy antagonist to the engineers, who were complete masters of the subject. Still, enough appears to convince us that the feasibility of laying and permanently maintaining these important telegraph lines has been satisfactorily made out.

Without troubling our readers with all the allegations on the one side and on the other, we may state that it appeared in the result that a submarine cable can be laid between India (Rangoon) and Singapore in a depth of 40 fathoms over an even bottom. At the landing-places the water will, of course, be shallower, but there it is intended to lay a much heavier cable. A great point was made of the coral which exists in all the seas in which the proposed cables are to be laid; but the engineers assert that an examination of the Admiralty charts will satisfy any one that the different cables can be laid clear of the coral. It is sufficiently evident that coral can only be dangerous to an iron-covered cable in very shallow water, or where strong currents exist. Under other conditions the cable would lie at rest on the coral, and would not be damaged by it.

The Rangoon and Singapore line will have intermediate stations at King Island and Penang. The engineer to the Malta and Alexandria telegraph states:—"In my opinion the depth and nature of the sea bottom between Rangoon and Singapore are more favourable for laying and maintaining a cable than between Malta and Alexandria." He goes on to state that only one of the sections of the Malta and Alexandria line has ever had anything go wrong with it; and that though the line has been laid over three years, the working of that section has been interrupted in all for only 137 days, which he states would have been reduced to 30 days had a steamer been available for repairs on the spot. We believe that this contrasts favourably with the working of most land-lines. From Singapore it is proposed to lay cables to China in one direction, and to Australia in the other. As regards the line to China, it was admitted that the cable can be laid in a depth of 50 fathoms, and over an even bottom, at which depth Sir C. Bright states that "a submarine cable can be repaired without difficulty, or be picked up and laid down again at pleasure." The line to China, as well as all the lines under discussion, will be divided into sections of 400 to 500 miles, as to which it is stated in one of the letters:—"The longest proposed section will be shorter than one of the sections of the Malta and Alexandria line, while most of them are not longer than the cable connecting this country with Denmark." It is not, however, seriously disputed in the correspondence in question that a cable can be laid and maintained between India and Singapore, and thence to China. The dispute turns mainly on the line between Singapore and Batavia, and from the east end of Java to the head of Gulf Carpentaria in Australia.

As to the line between Singapore and Batavia, it is asserted that the cable will lie in water that is too shallow; and as to the line between Java and Australia, that it will lie in water that is too deep. The allegation as to the small depth of water between Singapore and Batavia is admitted. Sir C. Bright states:—"The water in this section is somewhat shallower than would be selected as a matter of choice, but not more so than is the case with the various cables crossing the North Sea and English Channel, connecting this country with Denmark, Hanover, Holland, Belgium, and France. It is true that these cables are sometimes injured, but they are speedily restored to working order." The depth between Singapore and Batavia is very little over 20 fathoms, and in portions of the sea it does not exceed 10 to 12 fathoms. As regards the line between Java and Australia, it is admitted by the engineers that the sea between Macassar and some 70 miles beyond Timor, being a total distance of nearly 550 miles, has not been sounded; but they state that there is no reason to suppose that this stretch is deep; the sea between Java and Macassar the charts show to be 40 fathoms in depth, and that between Timor and the head of Gulf Carpentaria to be 40 to 80 fathoms in depth.

With the exception, therefore, of some 550 miles, as to which we have no accurate information, the sea bottom between Java and Australia is known to be favourable.

There was some discussion as to the nature of the country between the head of Gulf Carpentaria and Brisbane; but it appears that it is now settled to within 100 miles of the Gulf, and that the Queensland Government has undertaken to carry a land telegraph across that country, the money for the greater portion of the line having been already voted by the Legislature.

As regards the permanence of submarine cables laid at a moderate depth, the only evidence we have is that the Dover and Calais line has lasted thirteen years, and works as well as ever. Deep-sea lines have failed because they could not be repaired. We know that the core of the cable, the copper and gutta-percha, are not destructible by any chemical action of the salt water. They can only be destroyed by mechanical violence. The outer iron covering, however, corrodes; and unless the outer protection with which the recently-manufactured cables have been covered preserves them effectually from contact with the salt water, that will always be a weak point in the complete success of submarine telegraphy. It is, however, a great fact to have determined that we can connect India with Singapore, China, and Australia by a system of cables which may nearly everywhere be laid in a moderate depth. We shall thus, at least, preserve our control over the cables. In a social, political, and commercial sense, as well as a scientific problem, it is right that these great works should proceed, and every one should desire to see them proceed successfully.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XIII.

A.D. 1825, June 18.—No. 5189.—Phillips, Charles.—"A certain improvement or improvements in the construction of a ship's compass." In order to provide against "the firing of cannon or any other circumstances" that "produce violent concussions, such as the sudden jerks produced by the paddles of a steam-boat, &c.," the compass box is mounted on a pivot (the upper end of which is the pivot of the needle), which rests upon a helical spring enclosed in the standard rising from the centre of the bottom of the wooden case. The reacting force of the helical spring is adjustable by means of handles connected with the bearing on which it rests by slits in the tubular standard, the bearing for that purpose resting in suitable notches in the standard. To adjust the centre of gravity of the compass to suit all weathers, a leaden ring is made to move up and down the compass box by palls falling into notched racks fixed vertically on opposite sides of the compass box. "Whenever it blows hard the leaden ring must be raised to such a height as to reduce the motion to that degree which shall be most convenient;" "in fine weather, on the contrary," the leaden ring must be placed "as low as it will allow." The "lubber's point" is placed on the upper arm of a pendulum whose centre of suspension is moveable in vertical guides, so as to enable the lubber's point to be adjusted "even with the upper edge of the compass." The pendulum bob is adjustable so as to make "the motions of the lubber's point correspond with those of the compass."

A.D. 1832, May 30.—No. 6269.—Preston, Grant.—"An improvement or improvements on ships' compasses." This invention "consists of improvements or additions to the common compass to prevent the vibration to which the compass is now subject, and which at present tends to prevent the correct action of the needle." The pin on which the compass card is suspended passes up through a tube or ring attached either to the agate cap or to the card, "and when the card has a tendency to vibrate, in consequence of any motion to the vessel, the lower end of the tube will come in contact with the pin, and stop such vibration. At the same time there will be sufficient play to ensure the action of the needle, and thus will compasses with my improvements applied be more correct in their action." The tube or ring may be either screwed into the agate

cap, or attached to the card by means of arms riveted to the needle. This improvement is applied to the dipping needle by the following means:—The needle, "in place of being affixed to the card," "is suspended on two axes," one on each side of the agate cap, there being an aperture in the centre of the needle to permit the agate cap to pass. The bearings of the needle axes are on the card, which is connected with the agate cap by means of a tube supported by arms from the card, as in the application of the improvements to the ordinary compass. The needle is thus "permitted to swing up and down, as is usual with this description of compass," and any vibration of the card is checked by the lower part of the tube coming in contact with the pin sustaining the card.

A.D. 1834, March 1.—No. 6570.—Pinkus, Henry.—The title of this invention is: "An improved method of or apparatus for communicating and transmitting or extending motive power, by means whereof carriages or waggons may be propelled on railways or common roads, and vessels may be propelled on canals." This invention relates to a pneumatic "railway," in which magnetic attraction may be employed, and which may either form "a complete system of railway in itself," or be applied to common railways or canals. "An extended tunnel, tube, pipe, or conduit," is laid down, which contains a piston. On one side of the piston the air is exhausted from the tube by suitable stationary engines and pumps at suitable distances along the line. To the piston is attached "a vehicle or machine," called "the dynamic traveller," which is in connection with "a car" on the outside of the tube called "the governor," to which the carriages, &c., to be propelled are attached. In the "pneumatic railway" itself, the rails are cast on the sides of the tubes; but in its application to existing railways or canals, the tube is laid down between the rails, or at the margin of the canal. The connection of the "dynamic traveller" with the "governor" is proposed to be made either by means of a longitudinal "pneumatic valve," through which a vertical arm rises, or by magnetic attraction. To apply magnetic attraction effectively, "the dynamic traveller" carries a frame of "horse-shoe magnets" "set transversely," with their poles placed as near to the under surface of the tube as possible. "A similar combination of similar magnets inverted," is attached or suspended "under the body of the governor," and in order to enable the space between the poles of the magnets in the two frames to be as small as possible, the upper part of the tube has a copper plate fitted air-tight into the opening instead of the valve. In the "dynamic traveller" soft iron may be used instead of the magnets. Electro-magnets may be used. Details are set forth of the manner of mounting the "dynamic traveller" and "governor," and respecting the "pneumatic valve," valves interposed at the extremities of a given length of tube called "station valves," and other matters.

A.D. 1834, March 13.—No. 6574.—Hawkins, John Isaac (*a communication from Daniel Harrington*).—"Certain improved instruments for facilitating the cure of disease by administering galvanic influence into the human body." "Various instruments" "compounded of" "any two differently oxidable metals" "by which galvanic influence is excited, the said instruments being respectively so variously constructed as to convey the mild galvanic influence in a convenient manner into or near upon the parts of the body on which it is desirable to operate." "The differently oxidable metals" (silver and zinc are instanced) being placed or pressed in contact with the body and with each other are enabled to generate electric currents by means of the natural fluids of the body. When required, these instruments are made to hold "warm water whereby the parts of the body operated upon may be raised in temperature." The forms of the acting surfaces of the apparatus described in the specification, and shown in the drawings, are suited to the part operated upon, and are smooth or indented according as the part of the body to which they are applied is hard or soft; more than one couple of metals are used in certain cases; and provision is made (when necessary) for the continuity or intermittent character of the electric current, according to the wish of the operator and during the action of walking. The contrivances for "electrizing" the passages of the human body are suited to their sinuosities, and when necessary made flexible. Besides plates, wires of the "differently oxidable metals" are twisted together, made into helices, and woven or platted together, "spangles" "overlapping one another" are sewn on to silk, and a mixture of the filings of zinc and silver (for instance) are cemented upon cloth, &c. The invention also comprises an instrument for puncturing the skin by suddenly letting go a steel spring from its detaining catch, which spring contains the "pointed ends of fine sewing needles, say, from a score to a hundred," and has its action regulated by a perforated plate and adjusting screw, so as to enable the skin to be punctured to the desired depth, and thus render the transmission of the electric current through the cuticle more easy.

A.D. 1837, April 22.—No. 7350.—Ulrich, John Gottlieb.—"Certain improvements in chronometers, consisting of:—1st. "A mode of ensuring a continued action of the balance of a chronometer by means of improved escapements or mechanism, which prevent the liability of the works being brought to rest by any sudden shock or circular motion of the instrument in the plane of the balance." 2nd. "Modes of compensating for the expansion and contraction of the balance spring under variations of temperature," which "allow of the employment of such materials for the balance *as are not subject to magnetic influence* (viz.), platina, palliadium" [palladium?] "glass, &c.;" "and also a mode of adjusting the compensating parts of the pendulum of an astronomical timekeeper." 3rd. "An improved mechanism for stopping the hands of a watch without interrupting the action." 4th. "A new mode of locking and unlocking the striking parts of such chronometers as report the time." 5th. "A mechanism for discharging the striking parts of an alarum or warning watch." 6th. "A mode of preventing the oxidation of the springs of chronometers, by covering them with a thin coat of some metal which is not liable to become oxidated." Coating by immersion.

A.D. 1837, April 29.—No. 7355.—Craufurd, Henry William (*a communication*).—"An improvement in coating or covering iron and copper for the prevention of oxidation." A coating of zinc is employed, which may be covered with a second coating of tin, or of tin alloyed with lead. The zinc coating may either be applied by means of fusion, or "as a paint, which then takes the name of galvanic paint." The metal to be coated is prepared by "scouring;" it is immersed "in water acidulated with sulphuric acid. The acidulated water should be heated in a leaden vessel, or it may be used cold in wooden vessels." The metal is then "thrown into cold water, scoured with sand and a piece of cork," "rubbed with a brush," and "thrown into clean water." Or the pieces of metal may be dipped in a solution of sal ammoniac, or dilute muriatic acid; they should be dried immediately after this last process "and coated with as little delay as possible." To coat iron or copper with zinc by fusion in an earthenware crucible:—"The zinc being melted, it must be skimmed carefully, and its surface covered with sal ammoniac or any flux;" the prepared pieces of metal are then "introduced into the melted metal," moved about, drawn out slowly, and, before the zinc surface "has become set," "thrown into clean water, and rubbed therein with a sponge or brush;" they are then dried rapidly in bran or sawdust; "a grated case with two handles" is employed for plates of the ordinary size; small articles are thrown into the melted zinc and sal ammoniac, taken out slowly with an iron skimmer, "put altogether in a reverberatory furnace, and covered with charcoal," then submitted to a red heat, shaken, and cleaned in a similar manner to the larger articles. Wire may be thus coated by being made to pass through the zinc, and cleaned as above. The "galvanic paint" "is composed of zinc powder well ground and mixed with the substances generally employed for painting;" "the oils distilled from coal tar," or coal tar itself with "spirit of turpentine" are preferred. The second coating with tin, or tin alloyed with lead, is applied to large articles, and to vessels to receive acids or food. The articles are moistened with a solution of sal ammoniac or muriatic acid, dipped rapidly in the fused metal and drawn out slowly, but not so that the zinc quits them: the fused metal is covered with a layer of fat or tallow. [In the "scouring" process, although no mention is made of electrical action in the specification, the immersion of the iron or copper articles in the dilute sulphuric acid, in contact with the leaden vessel, would generate a galvanic current tending to increase the solution of the iron or copper, and to perfect the process. The only way in which the term "galvanic paint" can apply is on the supposition that the iron or copper is partially laid bare, and thus exposed to damp, when the presence of the highly positive metal zinc in contact with the iron or copper would form a galvanic circuit, and prevent the solution or rusting of the iron or copper.] A "Disclaimer and Memorandum of Alteration" was enrolled June 14, 1839, by John James Siordet, John Charles Louis Meyer, and Robert Louis Siordet, to whom the interest in the patent was assigned by Louis Count Jelski, to whom Henry William Craufurd assigned the said interest; in which that portion which relates to "galvanic paint," and the second coating of tin, or tin alloyed with zinc, is disclaimed, and the invention restricted to the mode of "coating copper and

iron for the prevention of oxydation by immersing the same in melted zinc." Also, "the words, 'or any flux,' in the sentence, 'The zinc being melted, it must be skimmed carefully, and its surface covered with sal ammoniac or any flux,'" are proposed to be omitted, they having been "inserted with a view to state that any matter acting in a like manner might be used." A "Disclaimer" was enrolled September 2, 1848, by the same parties, who enrolled the above "Disclaimer and Memorandum of Alteration;" in which the "galvanic paint," the "second coating of tin, or tin alloyed with lead," also the words, "or any flux," are disclaimed; thus restricting the invention to "the mode of coating copper and iron for the prevention of oxydation by immersing them in melted zinc, having its surface covered with sal ammoniac."

A.D. 1837, June 6.—No. 7386.—Berry, Miles (*a communication from Edwin Williams on behalf of Thomas Davenport*).—The title of this invention is, "A certain improvement, or certain improvements, in obtaining motive power for propelling or working machinery." This invention relates to rotary motion obtained either by means of "galvanic" magnets alone, or "galvanic" magnets in combination with "permanent" magnets. This invention consists of a number of electro-magnets fixed radially on a rotating shaft, and segmental permanent magnets ("galvanic magnets" may be used) fixed to the frame supporting the rotating shaft. The motion of the rotating magnets is made to take place, by the approach of their poles to poles of the fixed magnets of opposite names; for this purpose the rotating "galvanic" magnets are made to change their polarity at proper times by the motion of plates (in metallic connection with the conducting wires surrounding the "galvanic" magnets) against fixed segmental plates, corresponding in number and position to the number and position of fixed segmental magnets, which segmental plates are connected in a suitable manner with the poles of a galvanic battery.

A.D. 1837, June 12.—No. 7390.—Cooke, William Fothergill, and Wheatstone, Charles.—"Improvements in giving signals and sounding alarums in distant places by means of electric currents transmitted through metallic circuits;" they are as follows:—A five needle telegraph. The symbols are indicated by the simultaneous deflection of two of the magnetic needles whose coils are included in the circuit, the required letter being found on a dial at the point to which they converge. In this signal apparatus the needles move in vertical planes, they being heavier at the lower ends to enable them to point vertically when not conveying signals; stops limit the angular motion of the needles, and they are astatic, one being within the coil, the other exterior to it on the face of the dial plate. To complete the circuit, a combination of finger keys is used, by which the line circuit is broken at the same time as the voltaic battery and signal apparatus are interposed; and by springs and studs, in connection with the finger keys, the current may be made to circulate in either direction. Five line wires are used in the above telegraph (one to each needle coil), or each needle may be deflected separately by having a sixth line wire for the return current. A four needle telegraph on the same principle, with five line wires, is also described and shown. Methods of insulating and supporting the line wires are described and shown, consisting of placing them in a resinous cement in channels in the rails or post and rail fences; or in various shaped tubes or troughs, the wires being previously covered with cotton, and varnished. A method of deflecting telegraph magnetic needles by electro-magnets. The current is made to magnetise two horse-shoe electro-magnets placed opposite one another, with the needle between their poles; similar poles are opposite, and the deflection takes place according to the polarity (*i.e.* the direction of the electric current). A method of "sounding alarums in distant places." The detent of a clock-work is removed by an electro-magnet, on the completion of the circuit, and is again interposed by a spring on the ceasing of the magnetism; or a hammer is made to strike a bell by similar means. "Sounding alarums in distant places by the aid of an additional voltaic battery." A battery, devoted solely to working the alarum, and not belonging to the line circuit, has its local circuit completed by the electric current from the distant battery. For this purpose the line circuit deflects a needle on whose axis a forked wire is mounted, which completes the local circuit by dipping into mercury cups; or the local circuit may be completed by the evolution of gas (caused by the line circuit), forcing mercury in a U tube into contact with a wire; the tube is closed at one end, and has a bulb containing diluted sulphuric acid, into which the poles of the line wires are inserted. A method of connecting and disconnecting an alarum from the circuit in the needle telegraph, by a bolt connected to the alarum circuit raising a spring in the needle coil circuit, is described and shown. Methods of ascertaining the precise place of injury to the line wires are described and shown; the coils of needles, mounted as in the needle telegraph, are included in the circuit between two of the line wires, one of which is defective, a station battery being connected to them; various points in the circuit are tried until one is found at which the needle is not affected; half the distance between this and the last effective point is then tried until the injury is found. A voltameter may also be used to test the completion of the circuit. To distinguish between the line wires it is proposed to use varnish of various colours.

A.D. 1837, December 4.—No. 7495.—Booker, Thomas William.—"Improvements in preparing iron to be coated with tin and other metals." "A mode of heating the pickling liquor (diluted acid), and in preparing iron plates to be coated with tin and other metals, in such manner that the heat can be more uniformly kept than when heated by the direct action of a fire, by which greater uniformity of production be ensured;" and "a mode of submitting sheets of iron in such manner to the action of the pickling liquor as to ensure their being kept separate, notwithstanding a number of plates are in the pickling trough at one time, the sheets being put into the pickling trough one at a time." Over a fire-place, having a door, ashpit, side flue, and chimney, is placed an exterior vessel containing a smaller vessel of lead, having a space all round it filled with water; the pickle (dilute sulphuric acid) is within the leaden vessel, and is thus subjected to the uniform heat of boiling water. To keep the plates separate they are placed in "grates" of lead or wood, having divisions, two in each division, but not in contact with each other. Every plate is dropped "on its lateral edge singly and separately." After pickling, the sheets are plunged into water, and "remain to be taken as wanted for the further processes of coating with tin or other metals." [Although no mention of electricity is made in the specification, the immersion of the iron plates in the dilute sulphuric acid in contact with the vessel of lead, generates an electric current in which the iron is the positive plate, and which therefore assists in and is favourable to the process above described.]

OCEAN TELEGRAPHS.

The partial success which has attended the attempts to connect England and India by a telegraphic wire seem to have revived the hopes which, after soaring so high five or six years ago, were cruelly disappointed by the failure of the Atlantic line and many subsequent disasters. After all the mishaps that have occurred, it is not surprising that any confident prediction as to future telegraphic achievements should be met with excessive suspicion; and when Sir Charles Bright wrote to the *Times* to say that the Indian telegraph was nearly complete—and that within three years China and Australia may, if we please, be in instant communication with London—it was quite a matter of course that he should be answered by a critic enjoying a preternatural sharpness of vision for the difficulties to which Sir C. Bright was a little blind. Mere spectators, who are neither stimulated by participation in telegraphic speculations nor terrified by the recollection of losses incurred, find it difficult to forego the hope that, sooner or later, all that has been dreamed of universal telegraphic communication will become a working reality. There is a fascination about the very magnitude and audacity of the larger schemes which captivates the fancy, even when it fails to secure actual co-operation. But there is better warrant than any hopes and fancies for believing that the great problems in telegraphy will before long be grappled with, and, it may be hoped, with a better issue than attended some of the earlier premature attempts.

Those who have watched the progress of the practical science of telegraphy, though they see that enterprises of this kind are much too arduous to justify sanguine predictions, know that the time which has elapsed since the most conspicuous failures has not been wasted. With the exception of the Malta and Alexandria cable, and other portions of the line to India, nothing on a very grand scale has been attempted since the breakdown of the Atlantic and Red Sea cables; but not the less, perhaps all the more, on this account science has been making vigorous progress, the causes of past failure have been thoroughly ascertained, and the errors which vitiated the earlier efforts have now been completely exploded. Whether our engineers are yet in a position to promise us a net-

work of telegraphic wires over the whole earth, may be still a moot point; but this great preliminary stride has been taken, that whereas in 1857 almost everything connected with ocean telegraphy rested upon guess, it is now almost true to say that each separate danger has been measured, and the feasibility of almost the most difficult lines reduced mainly to a question of cost. No practical art ever reached this point without ultimately advancing much further, and though it would be rash to conjecture how many more years, and how many more failures, must bridge over the interval before complete success is attained, we believe that there is now less reason than ever to despair of the ultimate triumph of many of the boldest schemes. Out of nearly a hundred submarine cables that have been laid from time to time, it is true that not much more than half are now in working order; and, as a rule, the successful cables have been those of the strongest, the heaviest, and the most costly descriptions. Most of the long cables and deep-sea cables have broken down, but the causes of failure are known. Many of them can be avoided, though not without incurring heavier outlay than was once thought sufficient, and the rest are said to be in a fair way to be surmounted by the improvements in manufacture and the discoveries of science. Whether the projectors of telegraph schemes are not even now too confident of immediate success, nothing but the event can prove; but there are, at any rate, signs to be noted more hopeful than the calculations of sanguine engineers. The project of carrying a cable from Ireland to Newfoundland across nearly 3,000 miles of sea, with soundings occasionally of two and a-half miles, was by far the most audacious that has ever been conceived; yet even for this scheme, after losing a capital of £600,000, the Atlantic Company have succeeded in raising a second fund, and are now busily engaged in manufacturing a cable which is to be payed-out from the Great Eastern in the course of next summer. Every one must wish success to so courageous an experiment, and though it is undeniable that many grave risks still remain, it is equally certain that the principal dangers which caused the destruction of the old cable have been either removed or greatly mitigated. At every stage of its progress a submarine cable is hedged round with danger. There is first the risk of defective manufacture, then the chance of mishap in paying out, and last, but by no means least of all, the certainty of deterioration and ultimate destruction by natural or accidental causes after the cable is submerged. Each of these elements of hazard is undoubtedly much diminished since the abortive attempts of 1857 and 1858. Incredible as it seems, it is a fact that the old Atlantic cable was laid down without any preliminary test of its soundness of the smallest value. A single pin-hole in the coating of 3,000 miles of wire would be enough to ruin the whole enterprise, and until the cable lay at the bottom of the ocean no one could say whether such a defect did or did not exist. Since that time the whole machinery for securing perfect manufacture has been revolutionized. Continuous testing under water detects the slightest flaw at any point, and means have been found for determining with the utmost nicety the precise position of a fault, so that the evil may be remedied at any time until the wire is absolutely out of reach. Practically, there is now no difficulty in ensuring the perfect soundness of a telegraphic cable up to the moment when it it is payed out over the ship's stern.

The second class of risks, those incidental to the laying of the cable, have in great measure been due to neglect of scientific precautions, and are almost entirely obviated now by the use of much stronger cables than were formerly in vogue. The new Atlantic cable, for example, thought very slight in comparison with many others, will be more than twice as strong and nearly twice as heavy as that which was for a time at work, while its weight in water, on which the strain depends, will be scarcely increased at all. But the really formidable risk is that of more or less rapid injury after the submergence. That the wire will be successfully laid, and will remain for a greater or less time in working order, may, in the absence of special ill-luck, be reasonably expected, but very few data exist for forming any opinion how long it will stand. With a mile or two of water above it, it will be safe from the accidents that so often damage more accessible cables; but in this case injury is ruin. Iron will rust, and insects will gnaw, even at the bottom of the Atlantic; and there is, besides, the possibility that the strongest rope of iron and hemp may give way when it lies stretched across the uneven rocks which will probably form some portion of its bed. The great safeguard against dangers such as these is to make the rope very thick and strong; but, in the case of an Atlantic cable, not only the extravagant cost, but the difficulty of stowing on shipboard, and laying 3,000 miles of very heavy cable, rendered it quite impossible to carry this precaution nearly so far as has been done in all the most successful cables. Certainty of wearing out sooner or later; uncertainty how soon the end may come; absolute impossiblity of repairing damages—these are the conditions of the problem. But, after all, the difficulty is reducible to a question of cost, and it must be presumed that those who have ventured once more on the enterprise have done so on the calculation that their cable will be long-lived enough to pay for its construction. Actual experience has shown how very large an income may be realised out of a long cable when in working order, and it is quite possible that a comparatively short term of years would remunerate the Atlantic Company for their spirited outlay.

While experience has thus encouraged the boldest of our telegraph projectors to a renewal of their experiment, under circumstances at any rate much less unfavourable than those of their first essay, it has led other engineers to the conclusion that, for the present at any rate, the safest course is to avoid deep water whenever that can be done. The Malta and Alexandria line was laid on the principle of never exceeding a depth of 100 fathoms for more than a few miles. At the same time, the sheathing was intended to be strong enough to allow of the cable being picked up and repaired at almost any point, as has already been done on more than one occasion. Whether the requisite strength will be retained after a few years of corrosion may be doubtful, but though the limit of danger may have been approached too closely in this particular case, the principle of keeping a cable always accessible for repairs is obviously right, as taking away much of the extreme hazard of such speculations. The controversy in the *Times*, to which we have already referred, raises a very interesting question as to the feasibility of laying telegraphs all over the world without abandoning this useful precaution. If Australia and China can be reached across shallow seas, the Atlantic will be the only deep ocean which it will be necessary to cross. Sir Charles Bright asserts that a route may be selected in comparatively shallow water all the way to China, on the one hand, and to Australia on the other, and that for the most part the inevitable deep seas and coral reefs exist only in the imagination of his critic. The project seems to be to creep in fifty-fathom water from Rangoon, along the coast of the Malay peninsula, to Singapore; and from that point to diverge with one line to the left, by the coast of Cochin China and China Proper, to Hong Kong, and with another, to the right, through Java, and thence by the island of Timor to the Gulf of Carpentaria. According to Sir Charles Bright this last section is the only one where deep water cannot be avoided, and even there he insists that the difficulty would occur only over a distance of seventy miles; so that the cable would be accessible for repair in every other part, and a fault in the worst possible position would not involve any more serious loss than that of seventy miles of wire. It seems to be acknowledged that the soundings are by no means so complete as would be desirable for laying such a cable, but if Sir Charles Bright is right in saying that shallow water is known to exist in all but this short portion of the projected line, there is certainly nothing, in an engineering point of view, to prevent the cable being laid within the three years claimed as sufficient for the work. The occasional or even the frequent occurrence of coral on the route would be rather a financial than an engineering difficulty. It is known that cables can be made strong enough to lie uninjured on a coral bed, and we have no doubt that to lay a cable from India to Australia and China, and to keep it in repair, is a feat quite within the compass of modern science. The completion and maintenance of the Indian line is a matter of much greater doubt. A message sent from Kurrachee on the 27th of September did, it seems, reach Bagdad on the 3rd, Constantinople on the 7th, and London on the 9th of this month; but before the speed upon this line can be materially improved, the Constantinople and Bagdad telegraph must be made secure and effective, and 150 miles of wire must be laid across the Valley of the Tigris, between Bagdad and the head of the Persian Gulf. A more hopeful prospect is afforded by the continuation of the Russian line through Persia to the shores of the Gulf, which is expected to be finished in a few weeks. It is not many years since the notion of receiving our earliest Indian news through a Russian channel would have filled English statesmen with consternation, and, though a telegraph by any route would now be heartily welcomed, it would be more desirable to have a line free from the danger of interruption in the event of a European war. When the Indian telegraph is securely established, by whatever route it may happen to go, the extension to China and Australia would not seem to be attended by any insuperable difficulty; and, if once these lines and the Atlantic

telegraph were laid, nothing but comparatively easy work would remain to complete a network which would leave New Zealand and the Cape almost the only places in the world of any importance excluded from the telegraphic circuit. For the realisation of these, like most other engineering visions, time and money are the only things wanting.

Telegraphy, after all its failures, and mainly through its failures, has passed out of the merely engineering into the commercial phase. Its task now is to prove, not only that this or that cable can be made, but that it can be made to pay. The renewal of the Atlantic enterprise shows that there are capitalists who have faith enough even in that hazardous undertaking to embark in it once more, and, although the Government is not likely to carry its own ventures farther than it has already done in the laying of the Malta and Alexandria cable, private enterprise may be trusted to complete any telegraphic line which promises a reasonable return for the risk incurred. Every year, by supplying fresh experience, reduces the risk of this class of undertakings, and the time must sooner or later come when even the vast scheme of carrying our electric wires as far as China and Australia will be no longer disparaged as the dream of a poetical engineer.—*Saturday Review.*

ON THE INFLUENCE OF TEMPERATURE ON THE ELECTRIC CONDUCTING-POWER OF ALLOYS.

BY AUGUSTUS MATTHIESSEN, F.R.S., LECTURER ON CHEMISTRY IN ST. MARY'S HOSPITAL, AND CARL VOGT, PH.D.

(*Continued from page* 187.)

The value given for the conducting-power of one alloy (lead-silver, containing 30·64 per cent. of lead) in the Philosophical Transactions of 1862 is wrong. We not only used part of the same alloy employed for the former determinations, but also made and analysed a fresh quantity, and found the values for the conducting-power in both cases the same; the present value is therefore the correct one for the conducting-power of the alloy. The error made in the former determinations must have been that a wrong normal wire was noted down as the one with which the resistances of the wires were compared; for according to the data from which the conducting-powers were then deduced, those there given are correct.

In order to show in a clear manner the results obtained, and to explain the law which we have arrived at, we will give in the first place the following tables:—

Alloy.	Volumes per cent.	Conducting-power at 100°.		Percentage decrement.	
		Observed.	Calculated.	Observed.	Calculated.
Sn_6Pb	83·96 of Sn	8·38	8·28	30·18	29·67

These tables will require some explanation. Calculated conducting-power means the deduced conducting-power of an alloy, it being assumed that the conducting-power of a wire of any alloy is equal to the sum of the conducting-powers of parallel wires of the metals composing the alloy.

Under the term "calculated percentage decrement between 0° and 100°," we do not mean, as might be supposed, the mean of the percentage decrements which the component metals would suffer in their conducting-powers between 0° and 100°, and which would be, for nearly all the alloys experimented with, 29·307 per cent., inasmuch as it has been shown* that the conducting-power of most of the pure metals decreases between 0° and 100° by 29·307 per cent. (the exceptions to this law being thallium and iron, the conducting-powers of which decrease between 0° and 100°, 31·420 and 38·[illegible] per cent. respectively †). It is therefore clear that the calculated percentage decrement in the conducting-powers between 0° and 100° of most alloys, from the above assumption, must be also 29·307 per cent. It is, however, obvious, on looking at the observed percentage decrements, that the conducting-powers of the alloys, with the exception of those given in the first of these tables, decrease less than 29·307 per cent. between 0° and 100°. In order to avoid repetitions, instead of the above value (29·307), we have inserted under the heading "calculated percentage decrement" that deduced from the following law:—

The observed percentage decrement in the conducting-power of an alloy between 0° and 100° is to that calculated between 0° and 100° (viz., 29·307) as the observed conducting-power at 100° is to that calculated at 100°.

Or writing the above in symbols,

$$Po : Pc :: \lambda_{100^\circ} : \lambda'_{100^\circ}, \qquad (1)$$

where Po and Pc represent the observed and calculated percentage decrements in the conducting-power of the alloy between 0° and 100°, and λ_{100° and λ'_{100° its observed and calculated conducting-power at 100°, Pc is, as just stated, equal to 29·307 in nearly all cases, the exceptions being with the thallium and iron alloys.

If the values so deduced be examined, it will be seen that those given in the first table for the observed and calculated percentage decrement agree very closely with each other, as well as with the mean value found for the percentage decrement in the conducting-power between 0° and 100° of the pure metals—viz., 29·307. This is just what we expected; for these alloys conduct electricity, as will be seen from the table, in the ratio of their relative volumes, and therefore their conducting-powers ought to decrease between 0° and 100° in the same percentage amount as that of the mean of their components.

On looking at the second table, which contains the alloys made of the metals belonging to the two classes, we find that, as long as there is no change in the conducting-power of the metals lead and

* *Loc. cit.* † Philosophical Transactions for 18[illegible].

tin by the addition of another metal, the conducting-power of the alloy decreases between 0° and 100° 29·307 per cent., but the moment the alloys show a greater or smaller conducting-power than that of pure lead or tin, then the percentage decrement is less than 29·307. Again, the alloys of tin or zinc with copper containing small amounts of those metals follow approximatively the above law; and on referring to the curves* which represent the conducting-powers of these alloys, it would appear that, starting with the metal whose conducting-power is greatly altered by a small addition of a foreign metal, the above law, as just stated, is approximatively true for all alloys as far as the turning-point of the curve, and from this point there is no agreement between the observed and calculated values. The difference between these values begins to show itself in some cases much sooner than in others; thus, with tin and copper after the addition of 1 per cent. of the former; with zinc and copper only after more than 10 per cent. of zinc has been added, and from these points it gradually increases with each addition of metal. What the exact law is which these alloys follow with regard to the property under consideration we are unable at present to state, but some of them at least show that the law we have put forth will hold good in their cases. Unfortunately the alloys of this class, containing large percentages of each metal, are exceedingly brittle and unworkable, so that no complete series of determinations with any set of alloys could be made; had we been able to do this with one or two series, we should, in all probability, have found the law which regulates the influence of temperature on the conducting-power of this group of alloys. With regard to those in the third table very little need be said, for the deduced percentage decrements prove that our law holds good for most of the alloys of this group. There are, nevertheless, a few remarks to be made respecting some of the values given in this table—namely, on those of the annealed wires. Elsewhere it has been shown that the conducting-power of hard-drawn wires of some metals is greatly altered by annealing them; with the alloys this does not seem to be the case, for the differences here are very small. On account of their smallness we have not thought it worth while to investigate this matter any further at present; for to arrive at such results as might show the connection between the effect of annealing on the conducting-power of alloys, and on that of the metals composing them, would require a long series of experiments. Although the percentage decrements in the conducting-power of these annealed wires are all somewhat higher than those of the hard-drawn, yet they may be considered the same, as the percentage decrements in the conducting-power of hard-drawn and annealed wires of the pure metals vary also in a small degree, but not always in the same direction. Thus, those found for silver were—

Hard-drawn.	Annealed.
28·67	28·82
28·44	28·67
27·82	28·21

We have calculated, as will be seen in the table, the percentage decrements in two ways—1st (*a*), using for the calculations the conducting-powers of the hard-drawn, and 2ndly (*b*), those of the annealed metals. The values so obtained for the percentage decrement do not differ very much from one another.

In calculating the results for the iron alloys, Pc has not been taken equal to 29·307, but for each alloy Pc has had to be calculated. Thus, for the 1st, iron-gold, which contains 27·93 volumes per cent. iron—

The conducting-power of 1 volume of iron may be said to lose between 0° and 100° 38·260 per cent.; therefore, 0·2793 volume will lose	10·686
That of 1 volume of gold may be said to lose between 0° and 100° 29·307 per cent; therefore, 0·7207 volume will lose	21·122
1 volume of iron-gold alloy, containing 27·93 per cent. iron, will therefore lose	31·808

On comparing the values obtained for the conducting-powers, &c., of the iron-gold alloys, the following facts are worth mentioning—their very low and almost identical conducting-powers, and the high percentage decrements found for the first two and the low one for the third. That there was no error in this value we convinced ourselves by remaking the alloy, which contained, according to analysis, the same percentage amount of iron as that given in the table, and the percentage decrement in its conducting-power was found equal to 4·04. Again, an alloy made by a well-known firm,† which gave on analysis 11·94 volumes per cent. iron, conducted at 0° 2·097, and lost between 0° and 100° 4·30 per cent. of conducting-power. Unfortunately, experiments with alloys richer in iron could not be made, owing to the brittleness of the alloys; the high percentage decrement in the conducting-power of the first two indicating something abnormal, which it would have been interesting to have followed out.

(To be continued.)

* *Loc. cit.*

† We are indebted to Messrs. Johnson, Matthey, & Co., of Hatton-garden, for many of the alloys experimented with. These were the first two, iron-gold, the platinum-silver, palladium-silver, and aluminium-nickel.

ADDRESS OF THE PRESIDENT OF THE NATIONAL TELEGRAPHIC UNION (AMERICA).

We have, on several occasions, adverted to the importance of union, and, in one instance, specially advised the establishment of an institute for telegraphers in England. Nothing has been done, however, towards realising our suggestions; but, perhaps when the advantages which result from such associations are shown, steps will be taken to give effect to our recommendations. Towards the close of last year an institution was founded in America, called the National Telegraphic Union. In the month of September last, a convention of delegates from many of the States was held in Philadelphia, under the auspices of the Union, presided over by Mr. J. G. Smith. The address of the president on this occasion contains some valuable information concerning the operations of the Union; and will afford a few hints to our readers who may be disposed to assist in the establishment of an institute for telegraphers:—

Gentlemen of the Convention,—Ten months ago the first telegraphic convention, elected from among the operators, that ever met in this country, came together in the city of New York.

At the time of the call for that convention a feeling of the necessity of an organisation, similar to that designed, was quite generally felt, but what the groundwork of action could be, what was really the amount of sympathy felt towards a Union, what under our peculiarly embarrassing situation could be done towards uniting ourselves, and what would be the tone and character of the Union, if established, were questions that few could settle to their own satisfaction. Sufficient, however, was ascertained to make it evident that an intelligent and respectable class among operators were anxious and willing to support a creditable Union; and the convention came together representing, through indirect action, a large circle of operators.

The sessions of the convention lasted three days, and it is a great pleasure to be able to say that, in my humble opinion, the first convention was creditable, not alone to the districts to which the members belonged, but to the profession generally; and, considering the newness of the enterprise, the field to be covered by their action, the dangerous questions likely to arise to nullify the preliminary measures necessary to be taken, they brought to the meeting a unity of purpose, an intelligent appreciation of the position and the duties, which would, I think, challenge a favourable comparison with any similar convention among any class of men.

Much of their success was undoubtedly due to the ability with which the presiding officer discharged his duties, and, although I regret that we are not similarly situated in that respect to-day, we still have his example before us, and I trust we may profit by it.

A constitution and code of bye-laws were adopted, which were well suited to the necessities of the occasion, and which were of such a character that any telegrapher could feel gratified at and pleased to support, and the result of which has been that, notwithstanding the difficulties to be overcome, we have, as a body, advanced steadily, although slowly, and have during this short time become a permanent institution.

The constitution was really the starting point—no organisation previous to that having effected that much upon any basis that promised good results—and from the adoption of that instrument we must date the existence of our Union.

We now number, of regular members whose names are enrolled upon the treasurer's books, 250, comprising twelve districts. Many others consider themselves members, and may eventually fulfil the duties required, but at present have not taken all the steps necessary to entitle them to privileges of membership.

Many of the obstacles in the way of rapid and thorough organisation of districts, and the carrying out of all the necessary steps which would leave no question of the existence of full rights and titles, is owing to inattention or lack of interest on the part of the officers of the districts.

The treasurer informs me that he now has in his hands, to the credit of the Union, $393.27. But very few members have received aid on account of sickness or disability, although some individual demands have been large through this source. For details of the financial affairs of the Union, I refer you to the report of the treasurer.

The experience of ten months has shown to us that in many ways we can now improve upon the production of our first essay; and this present convention is met, in accordance with the constitution, to consider what further, or other action, can now consistently be taken for our interest.

To complete and perfect the constitution and bye-laws, and thus establish

a permanent basis upon which our organisation can go forward more rapidly, will, I think, be found sufficient to occupy the attention of the convention at this session.

Our individual duties and our desire to be in no manner a hindrance to the general business of the profession (which we all know to be so conditioned at present that the continued absence of so large a body of practical men from its daily demands and requirements would be injurious), will be sufficient stimulus to prompt us to quick and decided action, so that we may return to our respective stations at the earliest possible moment.

One great impediment in the way of rapid and satisfactory progress has been found in the divided and scattered positions that we occupy. Many places contain but one member, one telegraph operator being sufficient for the locality; and in fact there are but a few places where a sufficient number of members are employed to make, when collected together, a respectable gathering for purposes of interchange of views and ideas. This has necessitated, on the part of the officers and those members who take the greatest interest, a large amount of correspondence and written communications, and, in consequence, a good deal of labour and devotion of all the time allowed from their daily duties, and still much has been left undone.

I would heartily recommend that some means be devised for more frequent, easier and more general communication among members and districts. Those situated in smaller places hear and know, in many instances, scarcely anything of what is going forward, and are very naturally, I think, inclined to believe that nothing is being done, and that no interest is felt in the affairs of the Union.

In this connection I would suggest that the publication at regular periods (say monthly) of a sheet containing from four to eight pages, in my opinion, would be the best means of overcoming these difficulties.

The publication could contain accounts of the proceedings at the regular meetings of the several districts, whereby all could readily see what interest is taken in other districts, and can profit by any valuable ideas or suggestions presented at other points.

Changes will no doubt be made in the constitution and bye-laws, which will render it necessary to issue new copies of them; and, apparently one of the most direct and thorough ways of issuing such documents would be to print them off, together with the proceedings of this convention, in an issue immediately after the close of the session; such issue, perhaps, to be the first of a regular publication. The advantages that such a paper would offer for the exhibition of whatever is progressive and ennobling among operators would accommodate what is, and for a long time has been, almost an absolute need and requirement.

The profession generally, and all those who are interested in the advancement of the science and practical application of telegraphing, could and would contribute to its columns.

Such a publication could be easily supported by the members of this association alone, and could be gradually increased in size with the advancement of the Union and the increase of contributions until, perhaps, we could realise eventually the full idea of a telegraphic review, as comprehensive as that proposed by the vice-president at the first convention.

That a publication of this kind would be of great advantage to us as an association seems almost indisputable. It would advance the standing of the Union; tend greatly toward the removal of the prejudice that now exists between companies and operators; and, properly managed, become a source of revenue.

I look upon it as almost an impossiblity for a telegraphic review to be established and maintained successfully in any other way than through the immediate support and interest of the body of practical telegraphers.

The questions of title, place and manner of publication, the proper person to take charge of its editorial management, price, and other details, can be disposed of without a great deal of discussion or loss of time.

Among the constitutional amendments which seem to me to be necessary will be that regulating the regular dues of members. At present it is fixed at 1 per cent. of the salary of the member. It cannot be legal or right to inquire into the private affairs of members, as this clause of the constitution makes it necessary to do. Our Union, like other institutions, cannot affect to govern the whole interests of the member. We have certain beneficiary provisions and certain regular expenses; these must be met by regular assessments. Moreover, one member has no greater privilege than another, and should not, therefore, be called upon to contribute more than another. Instead of 1 per cent. on the salary, I would recommend that some stated amount per month or annum be assessed.

Neither the constitution nor the bye-laws appear to be explicit and direct enough in their provisions for the organisation and incoming of new districts. Complaints are made that it is necessary to search over both constitution and the bye-laws in order to ascertain how a person or district can attach themselves to the Union, and then nothing absolute is ascertained. Some attention must be given toward remedying this defect, as it is of vital importance that too great obstacles should not be thrown in the way of those desirous of forming part of the association.

A great deal of discussion has ensued among members and districts relative to Article 7th of the constitution, in reference to members who may become incapacitated from their usual duties by sickness or accident. We plainly need some such provision in the constitution, but the amount set down is evidently too large. It is not in proportion to the assessments, and experience has proved that the Union could not afford to retain the provision as it now reads. I recommend that it be modified so as to equalise the advantages derived from the amount paid out by the Union. This could be done by providing for the payment of a nominal sum per week, say five dollars, and placing in the hands of the proper officer the power to limit the length of payments according to the resources of the treasury and the circumstances of the case.

I would suggest that the election of general officers should take place immediately before the adjournment of the convention, instead of upon the first day as provided. A change of the provision will be necessary to do this. It does not appear to me to be the proper time for the election of officers, as many are in doubt as to the ability of those who may be looked upon by a large number as the proper persons for the positions, and too much of the time of the convention is likely to be consumed by discussion and hesitation; whereas, during the recesses of the meetings, members can talk over the requirements of the positions and the character and quality of candidates. Again. As now provided, it looks as though intended that the officers so elected should enter upon their duties at the meeting of the convention, upon the same day. This evidently cannot be the proper interpretation, as the former officers could not make their reports.

At the last session, I am firmly impressed with the belief that a provision was passed authorising the payment of the expenses of delegates from the fund of the Union, but I do not see it in the copy of the constitution. This provision seems to be necessary, and I think a resolution regulating that matter should be passed, and should be allowed to include the expenses of the delegates to this convention.

In order to preserve as much as possible the credit and character of the Union, pains must be taken to investigate the moral qualifications of new members. It is my opinion that no person known to be addicted to drunkenness, even should he be the finest description of an operator (so far as writing and reading is concerned), should be allowed to become a member, unless strong proofs are shown of reformation. Nothing whatever is to be gained by the addition of such men, and nothing is lost by rejecting them. Cases will arise where men known to be good-hearted, intelligent, fine, practical operators, but addicted to this habit, desire to become members, and, although we may not desire to wound their feelings, yet the character of the Union is worth preserving, and when the fact becomes patent that we cannot accept such members they will reform themselves before asking admission, or must expect to be rejected.

Throughout the ten months that have passed since our organisation we have gained in the respect and esteem of the companies that employ us. A telegrapher to-day is not regarded in the same light that he was a year ago. The better class of operators throughout the country are joining our ranks. Our provisions are sufficiently liberal to allow all good men and telegraphers to come into the association, and we institute no unjust or illiberal measures, but only such as are necessary to our progress and the preservation of our standing and character. It will soon be said that those among telegraphers who are not of us must necessarily be defective or unreliable, and we shall find ourselves constantly and steadily gaining in the eyes of those we desire to influence, and progressing in the path that leads to substantial results.

Not being organised upon temporary ground, or for transient and momentary purposes, we need to employ wisdom and prudence in our considerations. Let us not look to present results so much as to the future. Our organisation is yet young, and by the measure of forethought and discretion that we exhibit, shall we be weighed by those who wait to either condemn us or to aid us. While we make no boasts, or threaten any interests, let us prove, by our intelligent action, that we are capable of what we have undertaken, and that the Union and profession are both safe in our hands.

To one occupying the position that I have in the Union, the opportunity has been open to accomplish much by individual exertion and perseverance. But I have been so circumstanced that I have not been able to give to the occasion and the duties the attention they have deserved and needed; and I sincerely hope that you will be able to find, for the ensuing year, some one capable of giving to the duties of the position the attention they require, and that they must have. And I trust that, by the time the convention meets again, we shall find ourselves benefited by our action, and our association growing in favour and in numbers. We must bear in mind that the best results generally come by slow process, but are none the less satisfactory or perfect.

In compliance with the suggestion of the president, a journal in the interest of the Union has been established. *The Telegrapher*, for that is its name, is a monthly, of a decidedly business character, promising to become a thorough representative of telegraphers, and the art with which they are identified. To the columns of this periodical we are indebted for the address of the President of the Union.

The *Louisville Journal* thus refers to the above Union:—"Among the many excellent movements which have been recently made for the intellectual, social, and business improvement of professional persons, the formation of a National Union by the telegraph operators of the country appears to us to be the most important. The phonographer and the magnetic telegrapher have become of commanding importance to the press, and consequently to all classes of society; upon their accuracy and fidelity depends the diffusion of historic truth. As may be presumed, the object of the

telegraph operators in forming their National Union is the advancement of their general interests, and the elevation of the standard of the profession which is productive of so much benefit to the business community. The preliminary organisation was made in New York, last November, by a few of the operators of that city, but since that time it has increased in numbers and strength with great rapidity. Branch districts have been formed in all the States of the Union, from Maine to Salt Lake City, and the number of applicants for admission is greatly increasing. The purposes of the Union are the supporting of its members in sickness and adversity, the elevation of the character and standard of the profession, and the advancement of the general interests of the fraternity in a manner that will produce beneficial results to the employers and employed. A fund for the support of operators in sickness, or while out of employment, is provided by a pro rata assessment on all the members, according to the salary which they receive. All members are pledged to exert themselves to obtain employment for such as are in need of it and deserving. As the peculiar nature of the business calls most of those persons engaged in it from their homes and friends, this provision will be of great benefit to those who, while among strangers, are stricken down with sickness. By the rules of the Union, no person is allowed to receive instruction from members who are not properly qualified and capable of performing correctly and creditably the responsible duties of the art. Of late years many persons claiming to be proficient have obtained employment by such means, and not only brought discredit upon themselves, but upon the whole profession, by their blunders and incapacity. If a proper and judicious course is pursued by the members of the Union, much good must result to themselves, and the interests of the telegraphs of the country will be greatly advanced. What will be to their interests will also be of profit and gain to the public; for, unless correct and reliable operators are to be had, but little service can be gained by the use of the telegraph—now almost indispensable in every-day business life. A branch of the National Union was formed in this city about three months ago. Operators from all parts of the State are included in the district, and some have already reaped the benefit of joining it by being cared for in sickness. The district is in a very flourishing condition, and numbers among its members the best telegraphic talent of this State and of Indiana. All good operators should join the association, and thus not only advance and improve their own interests and standing, but aid in perfecting the general advancement of the useful art of telegraphing."

THE ANGLO-AUSTRALIAN TELEGRAPH.

The discussion on this subject in the columns of the *Times* has been concluded; but since our last publication the following letters have appeared :—

Sir,—I find by your impression of to-day that I have two long-electric cable engineers to deal with—Sir Charles Bright rejoining and Mr. Henry Forde backing up. I have not the least objection to the opposition of any number of these gentlemen. Let us begin by looking to the results of their previous performances before we trust them with our money in laying down cables to China and the Antipodes. The great Atlantic cable was a total failure, accompanied by a heavy loss. No one has succeeded in picking up the two ends, or, as the case may be, its many two ends. It lies at the bottom of the ocean, to be traced by some future geologist in a future revolution of the earth's formation. The Red Sea cable gave one squeak, and for that one squeak the nation is burdened with an annuity at the rate of 4 per cent. for between 40 and 50 years. The cable itself is at the bottom of the Red Sea, along with the bronze of Pharaoh's chariot wheels, to be picked up by a geologist coeval with him who discovers the remains of the Atlantic cable. Next we have the Mediterranean cable, respecting which we have some candid details from its engineer, Mr. Henry Forde. This is not one cable, but virtually three distinct ones. The three sections or cables together give a length of 1,550 miles from Malta to Alexandria. The two first sections amount to 860 miles, giving each an average of 430 miles, and no fracture has taken place in them in the three years since the whole cable was finished. The third and last section, that which runs from Benghazi to Alexandria, 692 miles long, has been broken three times, producing an interruption in the whole line of 137 days, or about one-eighth part of the whole time since its completion. A telegraphic communication so uncertain is of little value, and not worth the cost of laying down. Mr. Forde states that the last section of his cable has been laid down, not in soft ooze, but on "a most irregular and uneven bottom, in places very rocky and exposed," and that he himself wished it to be laid down "in an uniform bottom of about 50 fathoms." The locality was selected by Captain Spratt, of the Royal Navy, the most skilful, accomplished, and careful of all our marine surveyors; and how can Mr. Forde tell whether the eastern portion of the Mediterranean would afford a better answering to his theoretical standard of a perfect bottom! Mr. Forde is not correct in the account he gives of the transfers of the cable originally meant to connect Rangoon and Singapore to the Mediterranean. The Home Government of India, very imperfectly informed, purchased at an enormous cost a cable to run from Rangoon to Singapore. It was shipped, but the vessel was wrecked and the cable damaged before leaving the channel. The Indian Government, by this time better informed about the difficulties of the Rangoon and Singapore line, backed out of the affair, and the cable was transferred to the Mediterranean. That the Indian Government has not the least intention of renewing the project is certain, for four years have elapsed and it has never been entertained. The cessation of the Chinese war has not, as Mr. Forde supposes, had anything to do with it. Were it practicable to establish a telegraphic communication with China, it would be even more useful now with our enlarged commerce, with the civil war in China, and war and commerce with Japan, than in any period of active hostilities with China. The Rangoon and Singapore line is still open to Sir Charles Bright, and, if he finds the coral reef and rocky bottoms which prevail among a hundred isles, and the south-west monsoon blowing boisterously for six months on a leeshore, more easy to deal with than Mr. Forde's shorter section from Benghazi to Alexandria in the comparatively placid Mediterranean, the world will be agreeably surprised. Sir Charles Bright's opinion of this route is confirmed by Mr. Forde, who considers it more favourable than the Mediterranean; but, as these two gentlemen have never visited the locality, I greatly prefer the opinion of the Indian engineers who have, and by which the Government has abstained from meddling with it. Now for the line from Singapore to China. According to Sir Charles Bright's project it is to consist of two sections; the first of these, ending at Saigon, will be about 700 miles long, and 300 miles longer than the average of each of the first two sections of the Mediterranean cable. For about the first half of these 700 miles the cable must be laid among islands, rocks, and coral reefs, for there is no possibility of avoiding them. The second section, ending with Hong Kong, will be about 1,000 miles long, or fully 300 miles longer than the section of the Mediterranean, which has been out of working order for 137 days in three years. Whether the bottom be smooth or stony, Sir Charles Bright cannot say, nor can anyone else; seeing that there are many islets and dangerous rocks in the direct route, the probability is in favour of the rocky bottom. Sir Charles Bright's explanation of the failure of the Dutch cable from Singapore to Batavia is lame and unsatisfactory. He ascribes its failure to the corrosion of the iron by the action of salt water, and the small size of the cable itself. The first fracture took place in a few days after the cable was laid down, and consequently when there was no time for the destruction of the iron by corrosion. The real cause of the repeated rupture of the cable was the inequality of the bottom, and the friction of the cable against coral and other rocks, aided in their operation by currents, a cause which is incurable, and might be aggravated by a heavy cable. Sir Charles and I differ as to the numerical amount of distances. He is the desperate lover of the poet who would annihilate space and time to meet his mistress; the mistress in his case being an electric cable of the newest construction. I make the whole distance from Java to the eastern side of Timor, fronting Australia, some 1,200 miles, and here he may divide his cable into as many sections as he pleases, but, with few exceptions, he will find a coral or rocky bottom, and coral reefs at most of his landing places. I feel obliged to Sir Charles Bright for directing my attention to the soundings lately made by that able surveyor, Captain Denham, between Timor and Australia. I will take his own account of this deep sea. There is, by his own admission, a gap in it of 70 miles, which even the skill of Captain Denham could not fathom. Over this abyss, with heavy cable of the newest construction in hand, he makes a clean spring with the same confidence that he would clear a Welsh brook or a Scotch burn with a running leap. I know nothing in grandeur equal to it, unless it be the achievement of the hero in "Paradise Lost" crossing the burning marl. With respect to the Australian land line, Sir Charles Bright tells us that the country is not a desert from Brisbane northward, such as I represented it, but that "the country is now settled to within 100 miles of the Gulf of Carpentaria." This is travelling faster than even Sir Charles's own cables. The country thus described as already settled, and settled by Britons too, embraces seven degrees of latitude and twice as much of longitude, nearly all within the tropics, with an average heat for the year of 80°, and 100° for the summer. And now I may explain why I have engaged in the present discussion. I did so in consequence of Sir Charles Bright's first letter, promising the establishment of a telegraphic communication with China and Australia in three short years' time. Such a letter coming from an amateur writer would have deserved no attention; but coming from a professional engineer, if mistaken, it was misleading, and merited a refutation. It is right, therefore, that the public should be put on its guard against the schemes of over-sanguine engineers, and therefore it is that I have written. C.

Oct. 19.

Sir,—The points at issue between your correspondent "C" and myself are now reduced to a very small compass. The sea between Timor and Port Essington, "almost every foot" of which he asserted before to be "so deep that it has never been fathomed," is now admitted to be shallow, except for the distance of seventy miles, which, he says, is "so deep that even the skill of Captain Denham could not fathom it." This triumph over the powers of the marine surveyor is altogether imaginary, inasmuch as he did not attempt to take any soundings within seventy miles to the south of Timor. Should it prove that the depth of water in any part of this short space is greater than will admit of the cable being raised for repairs, the loss, in the event of a portion needing to be replaced, would be trifling; but, as I said before, there is no reason to expect any very great depth in this locality. As regards the land line in Australia, the difficulties anticipated by your correspondent are now narrowed to the country between the head of the Gulf of Carpentaria and Brisbane; two-thirds the length,

between the latter place and Port Denison, are now under construction by the Queensland Government. The whole country in question is well known to be the best watered district in Australia, and cattle stations now exist throughout its length to within a short distance of the head of the Gulf. In respect to the line between Singapore and Hong Kong, "C" has abandoned his assertion as to the great depth to be encountered, but states that, for the first half of the section between Singapore and Saigon, the cable must be laid "among islands, rocks, and coral reefs, for there is no possibility of avoiding them." This I dispute altogether, and an examination of the charts will be conclusive that the cable can be laid quite clear of any such imaginary dangers. Nor is the existence of coral any serious objection, except in very small depths and where very strong currents prevail. Your correspondemt appears to be determined not to consult the charts of the seas between Rangoon and Singapore, although he has derived so much information by taking my advice to do so in the case of the Australian section; if he would be prevailed upon to do this, he would find that the cable can be laid in a depth of about forty fathoms over an even bottom of sand, shells, and ooze, as I stated before. I am now described by "C" as an ardent admirer of some poet who is said to have annihilated space and time to meet his mistress. This is because I have corrected some extraordinary exaggerations on his part as to the depth and distance. My measurements have been scrupulously exact, as well as all my other statements in reference to this subject. The possibility of constructing the lines within three years is taken great exception to by "C." I can only tell him that the telegraph cable lately laid by the Indian Government between Kurrachee and the head of the Persian Gulf was manufactured at the rate of fifty miles a week, and at this rate the whole of the proposed cables could be completed, even if the contracts should not be divided among several manufacturers, within two years. The laying of the different sections would proceed upon the completion of the several lengths, so that the last section could undoubtedly be finished within the time named. I have the honour to be, Sir, your most obedient servant,

1, Victoria-street, Westminster, Oct. 15. CHARLES T. BRIGHT.

CORRESPONDENCE.

THE OUTER COVERING OF DEEP-SEA CABLES.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—An amateur telegraph engineer would be somewhat puzzled as to what would be his proper course of action in the choice of a submarine cable (supposing the choice lay with him) if he were to read diligently the various contributions on the subject which appear in your pages; and this with respect to the outer construction no less so than as regards conductor, insulation, and general getting up. With respect to outer protective covering, it will sometimes appear that spiral iron sheathing is a mistake, mechanically and every other way; at another time we will be led to infer that the core (for deep water) may be laid in a nude state, and requires no covering at all; while anon we are told, in all soberness, that longitudinally protecting wires labour under objections that render the adoption of that style of cable wholly inadmissable. Of course your journal cannot be blamed for this heterogeneity of opposing doctrines; it should be open to record all views and opinions; at the same time, however, those which are erroneous, no less so than those that are doubtful, should have their errors exposed, combated, and exploded, if any real advancement is to be made in an enterprise which already, from this and similar causes, lags behind the age.

In last Saturday's impression appeared an extract from the Blue Book on "The External Protection of Deep-sea Cables," which winds up with so glaring an error as to render it absolutely necessary it should go undisputed no longer. It is quite certain "that the necessity for joints to be made in a cable whilst laying and after it is laid down is sure to occur, and must be provided for." This is an important and difficult operation whatever the nature of the cable may be. But we are led to understand that "in the ordinary twisted cable a splice can be made almost as secure as the original cable;" and this probably need not be quibbled about, as, by virtue of its very structure, it offers peculiar facilities for making good joints, if the maker is anything of a workman. What follows, however, must be taken exception to, as the implied difficulty in one case is really no greater than in the other. "Longitudinally covered cables will necessarily present greater difficulties. * * * When three or four wires are included in the same covering, a defect in any one wire renders it necessary *to cut the entire cable*, and this difficulty is, no doubt, an objection to this kind of cable." Well, if it were "necessary to cut the entire cable," it certainly would present an insuperable "objection to this kind of cable." But this is altogether a mistake. It must be a queerly made cable that necessitates complete severance in order to join up one broken wire, and seems to imply such a conglomeration of materials, thrown together without system or order, as to render it as difficult to find the severed ends of the wire as to discover a needle in a bottle of hay; there is probably not a longitudinal cable yet invented to which this objection is strictly applicable; if there be, it certainly has not seen daylight yet. So far as our own cable is concerned, there would not be the slightest difficulty in joining the core, or the whole cable for that matter, at sea; while, so far from the fact of the severance of one of the external wires rendering it necessary to cut the whole cable, we beg to say that we could join up the broken wire with the most perfect ease, and in as short a time as that required in splicing a spiral cable; and would guarantee the cable to be as strong, if not stronger, at that particular point as at any other part of the unbroken line. Moreover, the extreme lightness of our patent cable gives it an immeasurable advantage over heavy spiral iron cables in the making of joints; it could be more easily managed, and would incur no risk of undue weight falling upon the core, as must inevitably be the case with the other.

We may be allowed to say also that this style of cable, although only weighing ·875 tons per mile in air, is nevertheless the strongest cable for its weight and diameter yet invented, having a tensile strength equivalent to upwards of 11,000 fathoms of its own length in sea-water, and is wholly free from the slightest liability to kink.

It is much to be regretted that erroneous notions should be set afloat on matters of so much importance. It is enough to bewilder and bemuddle impartial men who are striving earnestly to arrive at a correct notion as to the best kind of cable for deep seas. There has been enough said, and justly, as we think, to make the most courageous rather nervous in the matter of the old style of construction, while the same individual may be driven to his wit's end to know what to adopt if equally apparently valid objections be urged against another style obviously well fitted to supersede the old one; and hence we thought it high time to challenge an absurd statement which has not a tittle of foundation in fact, but which has nevertheless gone undisputed these four or five years.

We are, Sir, yours respectfully, WELLS & HALL.

MAGNESIUM AND ITS LIGHT.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In your article on the magnesium light I observe that you mention the principal photographs which have been taken by its aid, and the fact also that the President of the British Association sat for his portrait during the lecture delivered by Dr. Roscoe at Bath; but you have omitted the name of the photographer. As I believe, I was the first to bring this metal into actual use for photographic purposes, and as you refer only to those photographs which I have taken, I think that I am at least entitled to have my name included with those mentioned who have interested themselves in practically demonstrating the value of the magnesium light for photographic and other purposes.

The experiment you refer to, as comparing the magnesium with the electric light, was made by myself, partly for the purpose of testing the value of Mr. Grant's lamp for burning the wire, and also to compare the two lights, which I had never previously had the opportunity of doing.

The electric light from sixty cells of a Grove's battery no doubt has greater illuminating power than the two burning points of wire; but the comparison was very satisfactory, as showing the superior *quality* of the magnesium light, as it was admitted by many present to be much whiter and purer than the electric light. A proper comparison of the two lights has yet to be made. For instance, what number of points of wire, burning at the same time, should be considered a fair proportion to the sixty cells of Grove's battery? Yours obediently,

Manchester, 19th October, 1864. A. BROTHERS.

TELEGRAPH CLERKS' SALARIES AS SECURITY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—A great benefit may be effected through the favour of your publishing a few words respecting an order just issued by a telegraph company, greatly detrimental to the interests of a large staff of employées. It is, giving notice that only a fortnight's salary is to be paid for the ensuing month; the remaining sum to be kept in hand, it is said, as a security against defalcations. This order, whatever may be its true origin, is, to say the least of it, unfair for the *present* employées, who had no idea of such a proceeding on entering the service, and they have no course to pursue but submit or resign. Many a poor manipulator, with a low salary, is expected to maintain a respectable appearance, and he is required to act with judicious economy to enable him to do so with his *regularly* paid stipend, and he will, by having such an amount stopped, as proposed, experience considerable inconvenience. The clerks are subjected to too heavy fines for errors, to require any further deductions. And I beg to suggest that, if even it is according to law, and supposing the money could be spared (although a fortnight is a long time), no company of recent formation should absorb the wages of its hard-working employées. I trust the order may be rescinded before its evil effects are visible. I have reason to believe that this simple statement will be endorsed by every telegraph clerk, and others, who peruse your journal, will accord us their sympathy.

Manchester. H. K.

A LIGHTHOUSE ON THE AFRICAN COAST.—The lighting up of Cape Spartel, the first lighthouse erected in the dominions of the Sultan of Morocco, took place on the 15th instant. The diplomatic corps and Governor of Tangier and suite were present. The tower is 79 feet high, with a fixed light visible 20 miles at sea.

TELEGRAPHIC NEWS.

Atlantic Telegraph Company.—The Iris, 25, sailing frigate, having been lent to the Atlantic Telegraph Company, instead of the Venus, 26, to be used in conveying on board the Great Eastern the Atlantic telegraph cable, has had the boilers which were temporarily placed on board removed by means of the floating shears, and will proceed round to the Thames, for the purpose of shipping the first portion of the cable.

Telegraph between Bombay and the North-West.—The telegraph line is now nearly complete between Bombay and the North West. A distance of thirty miles or so to the North of Gunpoorah now only remains to set up. The completion of the line had been delayed by the difficulties experienced in procuring carriage for the conveyance of material, both north of Ahmedabad and south of Agra.—*Homeward Mail.*

Opening of the Port of Avlona.—The *Levant Herald* of the 5th inst. observes :—"The Government, we understand, are about to declare Avlona a free port. Being the point of junction in Turkey of the telegraphic cable which connects the East and West by way of Italy, and being about also to become affiliated with the intended network of railway communication in European Turkey, the town and port of Avlona seem destined, beyond doubt, to a future of great commercial activity and importance."

The Anglo-Indian Telegraph.—The following important message, dated Bombay, 2nd October, was telegraphed from Suez on the 25th instant, at 1.30 p.m., but the route by which it reached that place is unknown, there being no mail from Bombay between the 29th of September and the 14th October :—"The Persian Gulf telegraph cable has been repaired. The land line is completed from Bushire to Teheran, and messages have come through to Bombay in twelve hours. The extension from Teheran to Bagdad will be finished next month, but the disputes on the frontier prevents communication with the latter city."

East Indian Railway Company.—In the half-yearly report of this company, to be presented to shareholders on the 31st instant, we find that in the North-Western Provinces the telegraph is in working order from the Kurrumnassa to Delhi. There are 52 stations at work, from which the number of messages sent amounted to 194,205, as against 124,878 from 45 stations in the previous half-year; the receipts from private messages amounting to Rs. 8,282-11-0, as compared with Rs. 8,935-3-0 in the previous half-year. On the Jubbulpore line, the engineer states that he has not, to the date of his return, received any official information of the despatch of the materials from England, or of the patterns of the various parts; but he believes Messrs. Waring Brothers & Hunt's agents have been advised of the shipments. Upon the arrival of the invoices, no delay need occur in the erection and working of the telegraph.

Supper and Presentation.—E. Gilbert, Esq., Superintendent of the Northern Division of the Electric and International Telegraph Company, was, on Friday evening, the 14th instant, entertained at supper by a select party. The occasion was his leaving the service of the Company, after seventeen years' labours, on accepting the appointment of Telegraphic Superintendent for the Scottish North-Eastern Railway Company, who are shortly to take the management of their telegraphic system into their own hands. Mr. Midgley, of the Telegraph Company's Office, presided, and Mr. W. G. Matthews, of the engineering staff, was croupier,—both gentlemen discharging their duties agreeably and efficiently. In the course of the evening, Mr. Gilbert was presented, through the chairman, with a valuable diamond ring, and handsome editions of "Chambers's Encyclopædia," and "Poe's Works." Mr. Gilbert, in accepting these tokens of regard, addressed the assembly in feeling terms, adverting briefly to his long connection with the Electric Telegraph Company, thanking his coadjutors for their invaluable assistance during that period, expressing the satisfaction it gave him to be so hospitably entertained, and to receive so marked an expression of good-will from those among whom he had laboured, but whom he was about to leave, in order to take the management in a more extended sphere of usefulness.

War Department Lectures at Chatham.—The following is the programme of the lectures to be delivered to the officers and men of the Royal Engineers at the Royal Engineer Establishment, Chatham, by Professor W. Pole, F.R.S., Professor F. Abel, F.R.S., Mr. F. Jenkins, and other eminent lecturers who have been engaged for that purpose by the War Department :—Oct. 18, "The Strategical Defence of England," by Capt. W. Hichens, Royal Engineers; Oct. 25, Nov. 1, and Nov. 15, "Railways and Railway Locomotives," by Professor Pole; Oct. 27, "Steel—Results of recent Researches on the Production and Constitution of Steel—English and Continental Steel Manufacture—Homogeneous Iron—Production of Steel by the Process of Bessemer, Krupp, Parry, &c.," by Professor Abel; Nov. 4, "Military History," by Capt. F. R. Chesney, Royal Engineers; Nov. 18, "On Copper, Lead, Zinc, Tin, Antimony—Alloys of those Metals—Conditions which regulate their Quality and Applications," by Professor Abel; Nov. 22, "On Gun Cotton, &c.—its History—its Properties, as compared with those of other Explosives—recent Improvement in the Manufacture and Application of Gun Cotton—Results of Experiments instituted with it in England," by Professor Abel; Nov. 24, "On Building Stones—their Characters and Qualities—Causes of the Decay of Building Stones, and Processes applied to their Preservation," by Professor Abel; Nov. 29 and Dec. 1, "On Signalling Instruments used on Land Telegraphic Lines," by Mr. F. Jenkin; Dec. 6, "On Signalling Instruments for Submarine Cables," by Mr. F. Jenkin. The following papers are also to be read and discussed on the dates named :—Oct. 21, "On Centralized Defence," by Capt. H. Hichens, Royal Engineers; Oct. 28, "On the Blasting of Chalk Rock by Gunpowder," by Lieut. T. Fraser, Royal Engineers; Nov. 4, "On some Experiments in Blasting in Brickwork," by Lieut. H. P. Knocker, Royal Engineers; Nov. 11, "On the different Electrical Methods of Firing Gunpowder," by Capt. R. M. Parsons, Royal Engineers; Nov. 18, "On Embankments for Retaining Water," by Capt. W. D. Marsh, Royal Engineers; Nov. 25, "On Gun Cotton for Blasting Purposes," by Lieut. Col. J. W. Lovel, C.B., Royal Engineers.

MISCELLANEA.

The Need of Means of Communication between Passengers and Guards of Railway Trains.—A reverend gentleman living at Gloucester has communicated the following extraordinary narrative to our (*Western Daily Times*) correspondent in that city :—"Travelling from London to Gloucester on the 19th instant by the express train, which left Paddington at 11.45, a scene took place which shows (if any additional proof were required) the importance of establishing some means of communication between the passengers and the guard. I had a second-class ticket, and, anxious to avoid the inconvenience of changing at Swindon, I took a seat in the through carriage to Gloucester. My fellow-travellers were two ladies, who were going, I think, into South Wales, and I had just settled snugly in a corner, and prepared for a few hours' quiet reading, when my attention was attracted by the entrance of a man in a sailor's dress, whose bloodshot eyes and savage mien told of drunkenness. I was on the point of seeking the guard when the fellow suddenly left the carriage, and, the guard coming up at the moment, I requested that he would not allow him to return; but to my surprise, almost at the instant of starting, the fellow burst into the carriage, followed by the guard, who warned him that if he did not behave properly he would be left on the road. Now, this was not a pleasant prospect. We were to run to Swindon without stopping, and were to be all this time caged with a drunken ruffian. But there was no help for it. In the course of some ten or twelve minutes the fellow vehemently proclaimed himself 'a Southern privateer, and an enemy to the —— English.' Rising from his seat he staggered over the feet of the ladies, and, confronting me, demanded what I had to say, threatening to 'smash my skylights' if I did not tell him my opinion, and flourishing his huge fist in my face by way of warning. I quieted him for a few minutes by getting him to tell us something of his early life. He said he was an Englishman, had run away from home when a boy, had gone to South America, and that when the war broke out he had taken service in a Southern privateer. His tale was mixed up with such oaths and blasphemies, that I was glad to withdraw my attention, whereupon, to my dismay, he produced a bottle of strong drink of some kind, and swore he would 'treat the company.' He put it to his mouth by way of showing us how to do it, and took a pull so hearty and so long, that he swallowed one-half of the contents. Declaring in words not to be repeated that the man or woman who did not drink should 'catch it,' he presented the bottle to each of the ladies. Having spent about ten minutes coaxing and threatening them, he turned to me. I expected I was 'in for it,' but upon my refusal he only expressed contempt for the 'old Jinnies,' and took the remainder himself at one gulp. This over, he prepared for smoking, and seeing it alarmed us, he amused himself for some time in throwing about half-burnt matches. He had learned the 'free and easy' habits of American society, and spat with an accuracy of aim that was undeniable, for he made my face the target on two or three occasions. When he had satisfied himself upon this head he grew heavy, and, stretching out his legs so as to take up one side of the carriage, he fell, as we delightedly supposed, into a sleep. I settled down to read, and had been, perhaps, ten minutes or so employed, when I was startled by a shriek and a spring from one of the ladies, and on looking up I saw, to my terror, that the fellow had suddenly opened the window, and had so far succeeded in getting out that, but for the presence of mind and courage of the lady, who had seized him by the hair, he would have been under the wheels in another moment. By uniting our efforts we were able to drag him in, but for full a quarter of an hour he fought and tore like a savage, leaping at the window, and we restraining him, till at last he was compelled to desist through sheer exhaustion. What a situation to be in! He then adopted a line of retaliation which was so grossly indecent and outrageous that I dare not describe it. The poor ladies (whose conduct exceeded all praise) huddled together into a corner, while I stood in front guarding them with a stout umbrella. I confess if at this moment the scoundrel had attempted to get out of the window again, I think I should have allowed him his own way. Providentially the engine-driver found it necessary to stop at Wantage-road, and I succeeded in obtaining aid, and had him removed. If we had been compelled to run all the way to Swindon, Heaven—who preserved us—only knows what might have happened." The writer adds :—"Now, I think you will agree with me when I say that it was a shameful outrage to put such a ruffian into our carriage, or into any carriage with civilized people. True it is we were only second-class passengers, but that is not sufficient reason—at least to us—why we should have been terrified almost out of our lives, and disgusted to loathing by the conduct of this drunken scoundrel. Never did I feel so utterly helpless. I put my head out of the window, and

I called till I became hoarse, and although the guard was within a few yards, we might have been murdered for any help he could have rendered, and all this in open day, and on the Great Western Railway. Perhaps if the wives and daughters of some of the directors had been in the carriage something might come of it, but of course as they travel in the first-class such a thing is not likely to happen to them; and yet poor Briggs's case shows us that even there people are not always safe. How long will the public bear this kind of thing? Surely it is our duty to call upon Government to compel the directors to action."

Fuller's Telegraph Computer.—Until this little machine has been seen it is scarcely possible to understand how completely a mechanical contrivance can be made to do all kinds of computations. Perfectly simple and intelligible in plan, it is capable of solving almost any problem in arithmetic. At one operation it does both multiplication and division. Interest is calculated to the most perfect nicety. The possessor of the machine may guage the contents of any vessel in a minute. The most intricate calculations are worked with the most perfect ease and simplicity. The principle upon which the machine is based is that of the ordinary sliding-scale, but its application is made completely intelligible and easy, while the form of the machine is most convenient for all office purposes. The peculiar advantages which this instrument possesses over other tables are thus enumerated by the proprietor:—It enables a person to calculate instantaneously—1. Interest upon any sum, or any kind of money, at any rate per cent. for any length of time. 2. The exchange of money with any country. 3. The exchange of weights or measures with all nations. 4. The exact loss or gain on cash, stocks, shares, real or personal property, at every possible fractional rate. It is invaluable as a check to even the best accountant, to verify and prove work done by another process. Very frequently inventors claim for their inventions powers which, on careful examination, they are not always found to possess. This, however, is not the case with Mr. Fuller's computer. It readily responds to every demand in the arithmetical way which is made upon it. We have only pointed out some of its advantages. Indeed, the purposes to which it can be applied are so numerous that it would be well-nigh impossible to enumerate them. No accountant's or merchant's office, or bank, or any place where rapid calculation is desirable, should be without it.

The Electric Light for Illuminating Large Buildings.—Professor Seely, of New York, has obtained a patent for an electric light on a principle which very strangely does not seem to have been thought of before as the best and by far the most economical mode of producing light by electricity. He employs the current generated by an ordinary frictional electrical machine, and obtains the light by interrupting the current. It has long been known that a very brilliant and steady light might be procured in this way, but the objecton to its use is the uncertainty in the action of the frictional machine. Dry air is a very poor conductor of electricity, and when a machine is excited in such an atmosphere the electricity will remain in tension for a considerable time. But moisture in the air conducts the electricity away, and when the moisture reaches a certain point the fluid is removed so rapidly that the machine will not work. Professor Seely's invention consists in devices for making the action continuous in all weathers. This is effected by surrounding the machine with a glass case, and keeping the air within the case dry by means of chloride of calcium or other hygroscopic substance. It has been observed that when the conductor of an electric current is interrupted in a way to draw a spark across the break, the brilliancy of the spark varies with the material by which the conductor is terminated at the break. Professor Seely is now engaged in experiments to ascertain what material will produce the most intense light. If the apparatus works according to anticipation a building may be lighted without any current expense, except the small power required to turn the electrical machines. As in mills driven by water there is always a surplus of power during the winter months, the only time when lights are required, there would be no expense for this light except the first cost of the apparatus, which would be quite moderate.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2607. A. Reynolds, improved mode of manufacturing sulphuric acid.

2616. J. Scarisbrick, improvements in apparatus for signalling on railway trains.

2634. W. Clark, improvements in apparatus for concentrating and distilling sulphuric and other acids, and all solutions in general.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1755. E. Burstow, an improved apparatus for communicating signals in railway trains.

2083. J. S. Farmer, improvements in the construction of railway signals, and improved means of signalling between passengers and guards of railway trains.

2165. J. Barber, improvements in communicating, watching, and signalling throughout railway trains.

NOTICES TO PROCEED.

1508. M. E. Bowra, improvements in tubes and caps made of india-rubber or other known elastic gum, and in their application to various useful purposes.

1538. W. J. Pughsley, improvements in obtaining sulphuric acid from the refuse "pickle" used in tin plate works, and also from sulphate of iron or "green copperas."

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

2656. L. Pulvermacher, improvements in apparatus for the production of galvanic and magneto-electric currents, and in machinery employed in making some of the apparatus.—October 23rd, 1861.

PATENT ON WHICH STAMP DUTY OF ONE HUNDRED POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

2707. J. Macintosh, improvements in the construction and laying of telegraphic cables.—October 24th, 1857.

COLONIAL PATENT.

524. J. Haworth, an improved method of conveying electric signals and telegrams without the intervention of any continuous artificial conductor.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

Experimentalist.—The best covered wire for coils may be obtained of Messrs. Wells & Hall, of Mansfield-street, Borough-road, S.E.—See their advertisement.

A Patentee.—It is an infringement to make a patented article for use or sale, though the said article be never used or sold.

Enquirer.—The character of the letters in which messages are printed by Hughes' printing instrument is sans-serif, having the appearance of the following sentence:—PROFESSOR HUGHES IS NOW IN FRANCE.

J. Lamb.—Henri V. Regnault, the French physician and chemist, was "the first to demonstrate that the latent heat of steam diminishes as the sensible heat increases, but in a slower proportion."

R. A. P.—There is little doubt of the existence of electricity in the rays of the sun and other sources of light; but it is not of quantity or intensity sufficient to affect your experiments. Mr. H. Kevil read a paper on the subject at the Bath meeting of the British Association, and demonstrated the presence of electricity in the rays of the sun by suspending needles in exhausted receivers and exposing them to the rays of light, when deflections of the needle, varying from 2 to 10 degrees, were apparent.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street, E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

THE ANGLO-INDIAN, AUSTRALIAN, AND CHINESE TELEGRAPH.

Now that the correspondence in the columns of the *Times* on this subject has ceased, we may be allowed to ask—What has been gained by the controversy? A cursory glance at the origin of the discussion may enable us to convey a more intelligible narrative of the arguments than could be communicated otherwise. On the 9th of October Sir Charles Bright wrote the *Times* that "a telegram had been received by Sir Charles Wood from Colonel Stewart at Constantinople, dated the 7th instant, conveying the substance of a message from Colonel Kemball at Bagdad, of the 3rd instant, reporting the reinstatement of telegraphic communication between Bussorah and Kurrachee, and announcing the receipt at Bagdad of a telegram from India, dated the 27th of September." After conveying this information, Sir Charles Bright proceeded to a description of the works in progress in connection with the Indo-European telegraph, and concluded his letter by the following observation:—"The Indian telegraphs, which connect together Calcutta, Bombay, Madras, Delhi, and all the principal towns in India, are now advanced eastwards as far as Rangoon, and the routes thence to China and to Australia, by way of Singapore, Java, and Timor, are almost entirely in comparatively shallow water, so far as the submarine part of the line is concerned, and do not otherwise offer any difficulty which should prevent our having daily telegrams from Hong Kong, Melbourne, Sydney, Adelaide, and Brisbane, within three years from this date."

This latter clause appears to have given umbrage to an anonymous critic, signing himself "C," who twits Sir Charles Bright with "imaginative" and "poetical" conceptions of the enterprise; takes exception to his anticipations; disputes the practicability of a line of telegraph by way of Singapore to China in one direction, and Australia in the other; and asserts that, in order to realise the comprehensive scheme, the engineer "will have to lay down, sometimes among coral reefs and sometimes in unfathomed sea, 5,000 miles of submarine cable and 2,500 miles of land-wire, making in all a telegraphic line of between 7,000 and 8,000 miles in length."

It is unfortunate for "C" that the data on which these conclusions are based are invalid. In the first place, he affirms that the proposed line between Rangoon and Singapore will of necessity be laid in great part on a coral bottom. This asseveration is directly at variance with the Admiralty chart (which indicates a suitable course over sand, shells, and ooze), and is contradicted by Mr. Forde, whose long experience in these matters gives weight and force to his opinion. Regarding this very section Mr. Forde observes, "The depth and nature of the sea bottom between Rangoon and Singapore are more favourable for laying and maintaining a cable than" the sea-bed "between Malta and Alexandria." Again, "C" urges that the cable to connect Singapore and Hong Kong, of an estimated length of some 1,500 miles, must be laid in very considerable depths in a locality frequently disturbed by typhoons; whereas by the route contemplated the distance will be increased nearly 200 miles, in order that a landing may be effected midway at Saigon, while the utmost depth in which this line will be laid does not exceed 50 fathoms.

One of the first purposes of a telegraph engineer engaged in submarine work is to ascertain depth by soundings, and afterwards to avail himself of a route which will admit of the cable being recovered for repairs in case of accident, for the art of telegraphy has not yet reached that stage of perfection which will allow of indifference to this precaution. The scheme proposed is, therefore, to proceed in 50 fathoms of water from Rangoon *viâ* the coast of the Malay peninsula to Singapore, and from that locality to extend divergent lines by the coasts of Cochin China and China Proper to Hong Kong in one direction, and through Java, and thence by the Island of Timor to the Gulf of Carpentaria in the other. Sir Charles Bright, in anticipation of any emergency, has selected a course as suitable for the proposed telegraph, and believes it to be "almost entirely in comparatively shallow water, so far as the submarine part of the line is concerned;" but herein "C" differs. Where he finds deep water he conjures up disasters, and where he discovers shallow water he predicates misfortunes. Exception is taken to the Singapore-Hong Kong section on account of great depths, and objection is urged to the Singapore-Batavia section on account of the shallow sea. It happens singularly enough that in his study of this subject "C" has omitted to consult the best authorities, or to avail himself of the information imparted by the most recent Admiralty surveyors; hence, his statements are unreliable, and his deductions from them erroneous. From Java, "C," in his simplicity, maps out a course direct from Batavia, evidently unaware of the long-existent line throughout the island. Between Timor and the Australian coast "C" says the sea intervening is "considered by experienced mariners to be one of the deepest in the world," while the engineer affirms that the water is shallow with the exception of about 70 miles south of Timor."

On the Australian coast "C" selects Cape York as the landing-place for the cable, and says that "a land-wire will have to be carried 2,500 miles from that point to Brisbane, Sydney, Melbourne, and Adelaide, to complete the entire undertaking." It is fortunate that the greater part of this length is already at work, all the cities enumerated being connected with each other at the present time.

"The distance from Timor to Port Essington (one of the intermediate stations on the route to the Gulf of Carpentaria) is from 700 to 800 miles, and the cable to form this connection," says the critic, "will have to be submerged in water so deep, that it has never been fathomed, and, for what any one knows, is unfathomable." Here, again, "C" is at fault. The distance is but (taking the highest estimate) 500 miles; while the whole of the sea between the Australian coast and Timor, with the exception of a portion varying from 40 to 90 miles from the island, is under 80 fathoms in depth, the greater part varying from 30 to 40 fathoms.

The foregoing may be considered the substance of the arguments. It is apparent that in the outset Sir Charles Bright sought only to inspire public confidence in one of the most important undertakings of modern times; while "C," from some motive, on the nature of which it would be unbecoming to speculate, has endeavoured to undervalue the statements and anticipations of the eminent engineer. It not unfrequently happens that a critic finds himself in a dilemma from having ventured too far on other men's domains. In his last letter "C" evidently acknowledges the peculiar predicament in which he finds himself involved, and thus explains why he engaged in

the present discussion:—"I did so in consequence of Sir Charles Bright's first letter, promising the establishment of a telegraphic communication with China and Australia in three short years' time. Such a letter coming from an amateur writer would have deserved no attention; but coming from a professional engineer, if mistaken, it was misleading, and merited a refutation." "C's" apology is equally unsatisfactory as the statements previously made, for it is qualified with an "*if*," which deprives his former observations of all weight, and renders his conduct in guarding the public against the schemes of over-sanguine engineers a work of supererogation. Throughout this controversy Sir Charles Bright has evinced a disposition to bear with his critic's shortcomings, and to afford him every information in order to enable him to become better acquainted with the subject—a course which commends itself to our approval. We have gone carefully over the arguments on both sides, comparing the estimates and soundings with the maps and charts, and can endorse the concluding observations in Sir Charles Bright's letter of the 15th ultimo, wherein he remarks:—"My measurements have been scrupulously exact, as well as all my other statements in reference to this subject. The possibility of constructing the lines within three years is taken great exception to by "C." I can only tell him that the telegraph cable lately laid by the Indian Government between Kurrachee and the head of the Persian Gulf was manufactured at the rate of 50 miles a week, and at this rate the whole of the proposed cables could be completed, even if the contracts should not be divided among several manufacturers, within two years. The laying of the different sections would proceed upon the completion of the several lengths, so that the last section could undoubtedly be finished within the time named." Having reviewed the correspondence, we again ask—What has been gained by the discussion? An answer seems difficult, but we have one—It has inspired public confidence in the gigantic work, has strengthened the reputation of Sir Charles Bright as a telegraph engineer, and proved to the world the utterly unreliable nature of anonymous criticism.

ON RAILWAY ELECTRIC SIGNALLING.

By W. H. Preece, Assoc. Inst. C.E.

The attention of railway managers to the power of electricity in facilitating and protecting the working of their traffic is becoming daily more fixed. The many accidents that have occurred which could have been obviated by the adoption of modern electrical appliances, the constant and repeated recommendations of the Government inspectors to improve the system of working, but, above all, the freedom from calamities which characterise those lines that have availed themselves of the services of the electric current, and the constant repetition of accidents upon lines that are deficient in these useful auxiliaries, have fairly produced a reformation in the opinions of our railway authorities. Electricity is in the ascendent. It is a power which, thoroughly understood and properly applied, can accomplish an immense amount of service in the working of a line. It supplies the only means that science possesses to enable us to carry out the "block" system in its entirety.

It is curious to observe how the term "*block*" system has become rooted in the language of railway lore. It cannot be said to be strictly correct. The "*space*" system, as opposite to that of "*time*," would have been more accurate. It probably arose from the necessity of "blocking," or pinning the needle over in the earlier systems, to protect the line, or what is now called "block" the line from following trains. The period which elapses between the passage of one train and another depends upon the distances at which the signalling stations are placed apart, and if these be made to correspond with the maximum amount of traffic likely to arise on any particular section of the line, the delay, if any should arise, would be reduced to a minimum. The London and North Western maintain their signalling stations at intervals of two miles. On the Charing Cross extension of the South Eastern Company they are less than a mile apart.

The "block" system is the plan by which trains are maintained apart by a certain and invariable interval of space, instead of an uncertain and variable interval of time. Most railways have hitherto been worked on the time system. Experience has proved this to be unsafe. The block system is the only safeguard against collision. Colonel Yolland, in his evidence at Egham, stated:—"The danger of running trains at intervals can only be obviated by the block system of telegraph."

Where fast express and slow goods trains are travelling over the same line, now through a thick fog, now up a wet incline, it is impossible to maintain that rigid interval of time which is essential to prevent collision. When a creeping mineral train breaks down in a long interval between two stations, it is frequently impossible for the guard to go far enough back to stop an advancing fast train from dashing into it. When, however, two trains, however rapidly or slowly they may be running, are invariably kept apart by an interval of two, three, or four miles, such accidents are impossible; breaksdown are harmless, and no mischief can occur beyond delay. Railway companies are very chary of introducing the block system, upon the plea that it produces delay, but practice shows that the delays it produces are not so excessive as those under the old plan. Instead of keeping the danger signal on for five minutes, and the caution for five minutes more after the passage of each train, the signal can be lowered to "all right" immediately the train is signalled out of its length, and trains can run with perfect safety at intervals of two minutes, or even less.

It is also urged against the block system, that anything which removes the responsibility from the driver, and distracts his attention from a straightforward look-out, must be objectionable. Now, those who raise this objection, ignore as an advantage on the open line what is admitted to be essential in a long tunnel, where the greatest caution is required, and where, when full of steam, the look-out is confined to the length of the driver's nose. If the system is advantageous in a dark tunnel, where the driver trusts entirely to the faithfulness of the "block," surely it must be useful where he has the advantage of the light and a clear look-out! But how does it remove responsibility from the driver? The signals are the same, and he has but to follow them, whether they are lowered at an interval of ten minutes, or after intimation that the section of line in front is cleared. Those who have introduced the system, and have received a practical exemplification of its merits, are found to advocate it strenuously, while its opponents are almost invariably found to have never used it at all. Practice makes wonderful changes in settled opinions.

I carefully avoid the use of the word "telegraph," in speaking of railway signals, because it is so difficult to induce railway authorities to associate the construction, the working, and the complication of the ordinary telegraph with the simplicity and the action of electric signals. A great amount of misconception exists as to the difference between the two. The following remarks occur in a leading article of the *Railway News* (Oct. 8, 1864), when dilating upon Colonel Yolland's remarks upon the Egham accident:—"The Government officer recommends the adoption of the electric telegraph as a ready means for keeping an interval of space between following trains. Under this system, the station in advance telegraphs back that the line up to that station is clear for a train to travel up it. But the electric telegraph itself is at best merely an auxiliary; and it is even possible that the 'affirmative signal'—which it is to a certain extent—of the electric telegraph may induce a false security on the part of the driver, and lead to serious

accidents, in the event of an incorrect telegram being sent along the line. It is very easy for a telegraph boy to make a mistake in a signal, and to send the message of 'all clear,' when the line is really obstructed."

Now these observations are very true for cases where the electric telegraph worked by boys is employed for signalling purposes, but they are totally inapplicable to electric signalling, properly speaking. In the first place, electric signals are never entrusted to a boy—they are invariably placed in the hands of the signalmen themselves. Telegrams do not pass to indicate that the "line is clear" or "blocked;" a permanent signal is made behind each train to protect it from any following train. The proper way to consider electric signals is to treat them precisely as distant signals worked two or more miles off. Thus, when a signal is put up to protect a train, it cannot be taken off until the train arrives at the end of the two miles. The idea of imparting a false security to the driver, or lessening his responsibility, is no greater with electric than with mechanical signals. The action of each is similar, only in the one case we use electric and in the other muscular force. Any system of signalling that requires the passage or spelling of words, or the asking of questions, must be based upon an infirm foundation. If any lines do adopt such a system, the sooner it is abandoned the better will be the security of the passengers. It is the adoption of imperfect systems of signalling that has principally caused the slow advancement of electric signalling, and prejudiced the minds of railway managers against its use. They have attempted to accomplish in a telegraphic manner what can only be done perfectly in a railway fashion. That electric signalling can be performed securely and promptly in a railway manner, will, I trust, be fully evident from the succeeding column.

The chief object to be attained in carrying out the block system is that of making the next station practically a distant signal, to protect the line from any following train, and on single lines from any meeting train. This could be easily carried out, were it mechanically possible to work a signal two miles off, and blow a whistle that could be heard that distance; but as this is impracticable, electricity has been made use of to supply the want. The moment a train enters a section of line its approach is announced to the station towards which it is going by the sounding of a bell or gong, and the line behind it is protected from any following train by a danger-signal being raised and maintained in that position until the train has passed clear of that section. This, it will be perceived, is just what is done by a distant signal within sight: the train approaches, the signal is put up, and it is not lowered until the train is clear. It is a very simple operation to perform, when the mechanical contrivances for effecting it are within sight and within reach; but great precautions are required when that subtle force, electricity, is used.

There have been many attempts made upon various lines to introduce a perfect and reliable system, but that we have not yet succeeded in obtaining the best plan is evident from the fact that scarcely two of our railway companies adopt the same system.

(To be continued.)

REPLY TO "CHEROKEE."

By Uncle Sam.

Lest it should be said that "Cherokee," the slashing Red Indian of the *Telegraphic Journal*, of the 1st of October, cannot be answered by any of your correspondents, I have ventured to reply to his article.

Firstly, I would remark that in the algebraic formula he quotes, the symbol f represents, not *electro-motive force*, but the *strength* (intensity) *of the current*—that is, the amount of work the current is capable of doing over and above the work expended in overcoming the resistances of the circuit. E is the *electro-motive* force of the combination composing the battery, or the difference of tension of its poles—the force which urges the current forward.

The formula itself represents the *strength of the current* in a battery of n (any number of) cells on "short circuit"—that is, connected by a short and thick wire, the resistance of which is so very small as to be inappreciable.

The first law quoted from Wheatstone may not arise from the formula, but if "Cherokee" disbelieve it, let him experiment for himself, and he will find it quite true.

The second law is also perfectly true, and I think not "clumsy." Experiment is hardly necessary to prove it, for it commends itself to one's common sense, that if a conductor is enlarged and shortened, its resistance is decreased.

Thus, the first difficulty vanishes when the law and the formula are correctly stated. I am not fortunate enough to have been presented with a copy of "Noad," so that I cannot say who is responsible for the error.

"Cherokee" next questions the law that a battery will do the most work when the external resistance is equal to the battery resistance. Part of his difficulty arises from the error which I hope I have set right, and I think the remainder will be lightened, if not removed, by considering the law to refer to a *given battery*, in which all the elements are fixed, so that neither R, D, nor S are variable. The law then comes out true, though, as I have elsewhere shown, it is deceptive in practice, or at least in telegraphy.

I confess I do not see where "Noad" is wrong in the next case. Nothing is more easy to prove experimentally than that when the external resistance is inappreciable, one cell will do as much work as fifty—that is, as much *exterior* work, such as deflecting a needle, because each cell brings its own resistance with it, and the additional electro-motive force of each one is employed in overcoming its own resistance.

n E is a tension, not the same as E, but one n times as great. The internal (battery) resistance is also n times as great. But in the formula now given, R does not represent the same thing as in the first formula. It now stands for the total resistance of the battery, instead of the specific resistance of the fluids in the cells. Who is accountable for this confusion?

Give R its proper value, and I think "Cherokee" will acknowledge that his difficulty vanishes, for r, the exterior imperfect conductor, must have clearly, judged by common sense even, less comparative effect in increasing a resistance, R, than one n times as great. To employ the same style as "Cherokee" himself uses, an inch makes comparatively more difference in the length of an article in your journal than in that of an Atlantic cable.

Finally, is not he making fun of us? if not, will he explain his algebraical puzzle?

The Effects of Anæsthetics on the Human Constitution.—All anæsthetics act on the system similar to alcohol, the smallest effective dose produces exhilaration, a little more great excitement, which in different individuals manifests itself in a great variety of ways, a greater dose produces sleepiness, and the maximum dose perfect insensibility. The difference between nitrous oxide, and the other anæsthetics is, that the first being a supporter of combustion and respiration, stimulates the nervous system, and produces an increase of vitality, the others being non-supporters of combustion and respiration, depress the nervous system and bring vitality below the standard, and both with the same final result, *perfect unconsciousness;* the difference only is that the unconsciousness produced by the increase of vital action is harmless, and the same result produced by the depression of vital action is injurious, and may prove fatal; in other words, that the excitement or unconsciousness following the use of nitrous oxide is harmless in its results, and the excitement or unconsciousness following the use of ether or chloroform is connected with danger. It is a fact stated by Dr. Colton, who has administered the nitrous oxide to about 20,000 persons, more individuals than any other man living, that never any fatal result has followed; in the meantime, it is estimated that upwards of 3000 lives have been lost during the administration of ether and chloroform.

ON THE INFLUENCE OF TEMPERATURE ON THE ELECTRIC CONDUCTING-POWER OF ALLOYS.

By Augustus Matthiessen, F.R.S., Lecturer on Chemistry in St. Mary's Hospital, and Carl Vogt, Ph.D.

(*Concluded from page* 211.)

II. *Experiments on the Influence of Temperature on the Electric Conducting-power of some Alloys composed of three Metals.*

In the course of the previous experiments we were induced to try whether the influence of temperature on the conducting-power of the three metal alloys would be regulated by the foregoing law, and the following tables contain the results:—

Gold-copper-silver alloy, containing 50 volumes per cent. gold, 25 copper, and 25 silver (hard drawn).

Length, 341·5 millims.; diameter, 0·618 millim.

		Reduced to 0°.
Conducting-power found before heating the wire	10·6186 at 13·7°	10·6960
Ditto, after being kept at 100° for 1 day	10·6367 at 6·0	10·6681
Ditto, for 2 days.	10·5855 at 6·7	10·6232

T.	Conducting-power.		Difference.
	Observed.	Calculated.	
10·75°	10·5637	10·5617	+0·0020
33·52	10·4341	10·4346	−0·0005
55·15	10·3130	10·3148	−0·0018
78·35	10·1846	10·1873	−0·0027
97·52	10·0857	10·0828	+0·0029

$$\lambda = 10{\cdot}6220 - 0{\cdot}0056248t + 0{\cdot}0000009863t^2.$$

Gold-copper-silver alloy, containing 40·67 volumes per cent. gold, 39·81 copper, and 19·52 silver (hard drawn).

Length, 582 millims.; diameter, 0·625 millim.

		Reduced to 0°.
Conducting-power found before heating the wire	12·007 at 15·1°	12·109
Ditto, after being kept at 100° for 1 day	11·978 at 15·5	12·088
Ditto, for 2 days	11·915 at 16·5	12·026
Ditto, for 3 days	11·914 at 15·9	12·020

T.	Conducting-power.
9·0°	11·956
54·5	11·647
100·0	11·438

$$\lambda = 12{\cdot}017 - 0{\cdot}0069033t + 0{\cdot}00001111t^2.$$

Gold-copper-silver alloy, containing 3·67 volumes per cent. gold, 83·32 copper, and 13·01 silver (hard drawn).

Length, 764 millims.; diameter, 0·558 millim.

		Reduced to 0°.
Conducting-power found before heating the wire	44·820 at 18·4°	44·272
Ditto, after being kept at 100° for 1 day	42·994 at 17·1	44·348
Ditto, for 2 days	42·983 at 18·2	44·424
Ditto, for 3 days	43·047 at 17·0	44·395

T.	Conducting-power.
11·0°	43·591
55·5	40·300
100·0	37·560

$$\lambda = 44{\cdot}472 - 0{\cdot}081525t + 0{\cdot}0001240t^2.$$

Alloy.	Volumes per cent.	Conducting-power at 100°.		Percentage decrement.	
		Observed.	Calculated.	Observed.	Calculated.
Gold-copper-silver (hard drawn)	50 Au, 25 Cu, 25 Ag	10·14	62·89	5·20	4·72
Ditto	40·67 Au, 39·81 Cu, 19·52 Ag	11·52	64·84	4·82	5·25
Ditto	3·67 Au, 83·32 Cu, 13·01 Ag	37·39	70·09	15·54	15·63
Argentan	12·84 Ni*, 36·57 Zn, 50·59 Cu	7·46	44·44	4·39	4·98

The values in the latter table indicate that the law will probably hold good for most of the three metal alloys.

There is, however, one of the three metal alloys which we cannot pass over unnoticed—namely, that of copper-nickel-zinc or argentan (german silver). This alloy has long been used, on account of the small effect which temperature has on its conducting-power, for making resistance coils, &c. It is a somewhat curious fact that the conducting-power of this commercial alloy decreases less between 0° and 100° than almost any other alloy yet known, for in the course of this investigation we have only found the following, which show a smaller percentage decrement in their conducting-power than argentan.

The conducting-power of the platinum-silver alloy, containing 19·65 volumes per cent. platinum, decreases between 0° and 100° 3·10 per cent.

The conducting-power of the palladium-silver alloy, containing 23·38 volumes per cent. palladium, decreases between 0° and 100° 8·40 per cent.

The conducting-power of the iron-gold alloy, containing 10·96 volumes per cent. iron, decreases between 0° and 100° 3·84 per cent.

The conducting-power of the argentan decreases between 0° and 100° 4·39 per cent.

III. *On a Method by which the Conducting-power of a Pure Metal may be deduced from that of the Impure one.*

This part of our subject is an important deduction from the law

$$\mathrm{Po} : \mathrm{Pc} : : \lambda_{100°} : \lambda'_{100°}; \quad . \; . \; . \; . \; . \; . \; . \; . \quad (1)$$

for if we consider the two last terms of the proportion, and bear in mind that a small amount of another metal has very little or no effect on $\lambda'_{100°}$, when it represents the conducting-power of an alloy containing a very small percentage of the one metal, whereas it has a very considerable one on $\lambda_{100°}$, we may write the proportion

$$\mathrm{P} : \mathrm{P}' : : \mathrm{M}_{100°} : \mathrm{M}'_{100°}, \quad . \; . \; . \; . \; . \; . \; . \; . \quad (5)$$

where P and P′ represent the observed and calculated percentage decrements in the conducting-power of the impure and pure metals between 0° and 100°, and $\mathrm{M}_{100°}$ and $\mathrm{M}'_{100°}$ their conducting-powers at 100°. P′ is for most metals 29 307, or we may express it as follows:—

The percentage decrement in the conducting-power of an impure metal between 0° C. *and* 100° C. *is to that of the pure one between* 0° C. *and* 100° C. *as the conducting-power of the impure metal at* 100° C. *is to that of the pure one at* 100° C.

From the results given in the tables on page 210, we have chosen the following alloys to show that a small amount of foreign metal has no influence on the value $\lambda'_{100°}$, which may therefore be looked upon as equal to $\mathrm{M}'_{100°}$.

Alloy.	Volumes per cent.	Conducting-power at 100°.		
		Observed.	Calculated.	
Tin-copper (hard drawn) . . .	1·41 of Sn	48·89	69·78	Pure copper conducts at 100° 70·27
Zinc-copper (hard drawn) . .	5·03 of Zn	47·93	68·13	
Gold-copper (hard drawn) . .	1·37 of Cu	43·85	55·33	Pure gold conducts at 100° 55·90
Gold-copper (hard drawn) . .	0·71 of Au	62·25	70·54	Pure copper conducts at 100° 70·27
Platinum-silver (hard drawn)	2·51 of Pt	28·07	69·24	Pure silver conducts at 100° 71·53
Copper-silver (hard drawn) .	1·65 of Ag	65·81	70·66	Pure copper conducts at 100° 70·27

If now, as in the case of most commercial metals, the amount of impurity be much smaller than that in the table, then of course its influence on the value $\lambda'_{100°}$ is so small, that it may be entirely disregarded.

IV. *Miscellaneous and General Remarks.*

Having thus described the results obtained in this investigation, it only remains for us to make a few general remarks on them.

The percentage decrement in the conducting-power of alloys between 0° and 100° is never greater than that of the pure metals composing them; for on looking at the tables on page 210, we only find a few cases where the observed percentage decrement is greater than that of the pure metals composing the alloy, and in these the differences are so small that they are undoubtedly due to small errors in the observations, for the differences between the percentage decrements are not greater than those obtained for different wires of the same metal.

* Values found by analysis. Of this wire all our normal wires were made. According to former experiments (Philosophical Transactions, 1862, p. 5), the formula for the correction of conducting-power for temperature of this alloy was

$$\lambda = 7{\cdot}803 - 0{\cdot}0034619t + 0{\cdot}0000003951t^2.$$

The conducting-power of alloys decreases with an increase of temperature. This, however, is not strictly true for all alloys, for we already know of some where this is not the case—viz., a few of the bismuth alloys.

There must be, therefore, with some of the bismuth alloys some disturbing cause, which may act either in the one direction or the other, for on investigating one series the opposite effect is produced. This disturbing cause may be so great that, as in the case of another, it appears as if the conducting-power increases with an increase of temperature. Other alloys of bismuth and lead, rich in bismuth, give the same results. As yet, we have not had time to investigate thoroughly this curious property of the bismuth alloys; we hope, however, to be able shortly to do so, as well as explain the reason of these remarkable exceptions to the law, that the conducting-power of alloys decreases with an increase of temperature.

Respecting the parts the metals take in the conducting-power of their alloys, we are at present unable to give any definite data; we did hope at one time to have deduced them with the help of the results in this paper. It is scarcely necessary to point out that in many cases the composition of the alloy may be deduced from its conducting-power in the same manner as it may be from its specific gravity; for as

$$\mathrm{Po} : \mathrm{Pc} : : \lambda_{100^\circ} : \lambda'_{100^\circ}, \quad \quad (1)$$

then, if Po and λ_{100° be determined, Pc being known $(=29{\cdot}307)$, λ'_{100° can be calculated, and from it the relative amounts of the component metals for

$$\lambda'_{100^\circ} = \frac{xc + (100 - x)c'}{100},$$

where x represents the volumes per cent. of the one metal, $(100 - x)$ those of the other, and c and c' their conducting-power at 100°.

Thus the observed conducting-power of the gold-silver alloy at 100° is 14·05, and its percentage decrement 6·49,

$$\lambda'_{100^\circ} = \frac{14{\cdot}05 \times 29{\cdot}307}{6{\cdot}49} = 63{\cdot}45,$$

therefore

$$63{\cdot}45 = \frac{71{\cdot}56^{*} x + 55{\cdot}90^{*}(100 - x)}{100},$$

or

$$755 = 15{\cdot}66x,$$
$$48{\cdot}20 = x.$$

The amount of silver in the alloy was 47·92 volumes per cent. Again, the platinum-silver alloy, containing 19·65 volumes per cent. platinum, conducts at 100° 6·49, and loses in conducting-power between 0° and 100° 3·10 per cent.; calculating in the same manner the percentage amount of silver, we find it equal to 82·67 instead of 80·35. The values deduced for the percentage amounts only agree in a few cases well with those found by analysis, as slight errors in the determinations materially affect them; for instance, if the conducting-power of the gold-silver alloy were equal to 14·20 at 100° instead of 14·05, the volumes per cent. of silver deduced from that value would be 52·62 instead of 48·20, the value calculated from the latter number.

It may be as well to state in a few words how we determine to which class a metal belongs, whether to the lead, tin, &c., or to the gold-silver, &c., class; to do this it is only necessary to alloy the metal with traces of lead, tin, &c., and if the conducting-power be equal to that of the mean of the components, we say it belongs to the lead class; if, on the contrary, the alloy has a lower conducting-power than the mean of the components, we say it belongs to the gold-silver, &c., class. These are only some of one series of alloys which have a higher conducting-power than the mean of their components, and these are the amalgams.

In conclusion, we would point out that the law which we have deduced from our experiments only holds good in cases where the alloy may be considered a solution of one metal in the other, the metals belonging to the same class; when the alloy is composed of metals of the two classes, then the law no longer holds good (except for a few of the alloys), even if the alloy be a solution of the one metal in the other. The results which we have obtained and described in this paper fully bear out the views put forward in a former one regarding the chemical nature of the alloys.†

* Observed conducting-power of silver and gold at 100° (Philosophical Transactions, 1862, p. 24).

† Philosophical Transactions, 1860, p. 161.

THE OVERLAND TELEGRAPH TO AMERICA.

Referring to the proposed line of telegraphic communication, promoted by Mr. Collins, and to the action taken by the Government to refuse exclusive privileges to any foreign company, the *Colonist* observes :—

"The late despatch from the Secretary of the Colonies, objecting to the exclusive clause in the Telegraph Bill, will probably delay for a considerable period the completion of our telegraphic communication with San Francisco, and consequently with the East. It is the fault, however, of either the past or present Government that this difficulty has arisen, for the despatch in reference to the Collins line of telegraph, written on the 10th of February, arrived here some time previous to the passage of the Telegraphic Bill. By that despatch it was evident the Home Government would not sanction an exclusive privilege; and it was therefore exceedingly negligent on the part of the Executive at the time that this was not made known to the Legislature before the bill had passed both Houses. The Imperial authorities could not of course sanction an exclusive privilege to any line connecting these colonies with the neighbouring States, for that would have interfered with the Collins line connecting Europe with America by way of the Russian possessions and British Columbia. Mr. Cardwell's objection, therefore, on this head was tenable; but when the Secretary for the Colonies tells us that the strict enforcement of the non-exclusive principle between the British and American territory on the Pacific 'is peculiarly indispensable in British Columbia, through which her Majesty's Government may have to communicate in very critical times and in very important matters with her Majesty's naval forces on the Pacific,' he writes something that is very like nonsense. If the exclusive principle had been granted to a British Columbian line or one confined to British territory, Mr. Cardwell's reasoning would have been profound enough; but as the exclusion was only connected with lines running from British territory west of the Rocky Mountains to American territory similarly situated, the 'peculiarly indispensable' enforcement of the non-exclusive principle is scarcely based on proper grounds. The Home Government desire an overland telegraph through British territory. It is by this line—and this alone—that her Majesty's Government would communicate 'in very critical times with the naval forces on the Pacific;' but Mr. Cardwell must have seen a clause inserted in the Telegraph Bill to the effect that the exclusive principle was in no way to affect this intercolonial and transcontinental line.

"As the thing stands, we must make the best of it. We presume the California Telegraph Company will not recede from their undertaking even under this discouragement; but if they do it will devolve on the mercantile class here to risk the submarine part of the enterprise and connect with the telegraph which will shortly be in running order on Puget Sound. The advantage to Victoria of instantaneous communication with San Francisco as well as with the East is too palpable to require a word of comment, and the sooner the project is carried out the better. There have been too many hitches about the overland line to expect its completion before the expiration of another year. English companies have a cumbrous, unwieldy character about them that makes their progress especially tantalising to the people of a new country. In the summer of 1862 the Duke of Newcastle stated in the House of Lords that he expected by the time the Parliament would assemble in 1863 he would be in the position to inform their lordships that telegraphic communication had been established between Quebec and New Westminster. More than a year and a half has elapsed since the time the late Secretary for the Colonies anticipated would have seen the line in operation, but we seem to be still distant from the summit of our hopes. It is true the new Hudson's Bay Company is making an effort to carry a line of telegraph through; but beyond mere hearsay statements, there is nothing to lead us to believe in any immediate or energetic movement from this side of the Rocky Mountains."

HUGHES' SUBMARINE BATTERIES.

This invention consists in the construction and application of certain machinery, whereby submarine batteries, mines, or charges may be projected from the bows or other parts of a ship, discharged or drawn back into the ship with security, facility, and rapidity. For this purpose an opening is made in the ship at the requisite distance below the water line and inside of the ship, and opposite said opening a cylinder is attached, the length of which is equal to

about three times its diameter, and on the inner end of such cylinder is adapted a moveable water-tight cover, and towards its centre an ordinary sluice valve. The explosive material constituting the battery or mine is charged in a metallic shell, which is attached to the extremity of a rod. To place the battery ready for action, the sluice being let down, the external cover is taken off, the shell placed in the pipe, the cover run over the rod, (through a stuffing box provided for that purpose,) and the said cover is then bolted firmly to the pipe. The sluice being then drawn up, the battery is projected from the ship to the extent allowed by the rod.

The explosion of this battery is effected either by contact on striking any desired object, the shell in such case being provided with the usual means employed for igniting explosive materials by concussion, or it may be made to explode by an electric spark emitted from an electric battery in the ship, and conducted to the explosive materials by wires laid through the rod made hollow for that purpose.

In order to protect the cylinder from the effects of the explosion of the battery, a revolving shutter or escutcheon is hung outside the ship on a pin, and worked by a lever placed within the vessel. In order to give passage to the battery being thrown out or drawn in, it (the shutter) is raised; under all other circumstances it remains closed; besides arresting the force of concussion this shutter serves as a support to the rod in addition to the cylinder head and roller. When it is required to work this battery the rod is passed through the rollers, and the stuffing box in the cylinder head and the battery is united to the rod by means of the union joint, and thrust forward in the cylinder by means of the lever; the cylinder head is then run forward and bolted to the cylinder, the valve drawn up, and the shutter thrown back; the battery is run out by means of the handle to any desired extent within the limits of the rod; the shutter is then descended, and the swivel joint raised to its position, the extremity of the screw being brought in contact with the end of the rod. When it is required to draw in a battery, the shutter is raised, and the rod drawn in by means of the handle until the battery or charge is lodged in the inner half of the cylinder; the valve is then lowered so as to shut off all connection from the sea; the cock or pipe opened to allow the escape of water from such inner part of cylinder; the head can then be removed with safety, and the battery withdrawn. When the battery made use of is to be fired by contact or concussion the exploding material is hermetically enclosed within the case, which latter is provided externally with any of the ordinary appropriate contrivances for igniting gunpowder by percussion; and when the explosion is to be effected at any desired period, and at the command or will of the captain or officer in charge of the battery, an electric battery is used, ignition taking place by means of the passage of an electric spark through the charge produced by appropriate wires laid in the hollow rod.

TELEGRAPHS TO CHINA AND AUSTRALIA.

A PUBLIC discussion between parties holding different opinions on such a subject as the practicability of establishing submarine telegraphic communication between any given points is one of the most searching methods by which we can arrive at the truth. Such a discussion has been going on in the columns of a contemporary with reference to the practicability of laying and maintaining submarine telegraph cables between Rangoon and Singapore, and thence to China and Australia. A correspondent, "C," and two engineers, Sir C. Bright and Mr. Forde, have engaged in this discussion. "C" maintained the impracticability of the undertaking, and the two engineers its perfect practicability. It was agreed between the controversialists that, in order to secure permanent success to submarine telegraphs, it was necessary that the different cables should be capable of being laid in a depth not exceeding 50 to 100 fathoms, in comparatively short sections, and generally over an even bottom. The whole discussion, therefore, turned upon whether all, or, if not all, which of those conditions exist in the seas proposed to be traversed by telegraph cables. We must state that "C," who admitted that at first he had not examined the Admiralty charts, subsequently withdrew many of his allegations, and the points in dispute were in consequence very much narrowed. The whole of the seas in question have been surveyed and sounded, except a distance of some 550 miles between Macassar, in the island of Celebes, and 70 miles to the south of the island of Timor, which lies 400 miles off the northern coast of Australia. The termini of the proposed telegraphs are to be Hong Kong in China, and the head of Gulf Carpentaria in Australia, whence a land telegraph, of about 1,200 miles in length, is to connect the cable with the Australian telegraph system at Brisbane. "C" appears to have been frightened by the great length of the proposed telegraph systems as much as by anything else, and to have been utterly incredulous that it could be carried out in three years, as was asserted by the engineers. To this, however, Sir C. Bright gave a conclusive answer, stating that the Persian Gulf telegraph cable had been manufactured at the rate of 50 miles a week; that at that rate the cable required for the China and Australian lines would be completed in about two years, even if the contracts were not divided among several manufacturers; and that the laying of the different sections would proceed upon the completion of the several lengths, so that the last section could be laid within the time named. As regards the allegation of the great length of the proposed submarine systems, requiring about 6,000 miles of cable, the answer given was that the different lines would be divided into sections of 400 to 500 miles at most, or about the same length as the cable which connects us with Denmark, and the same length as some of the sections of the Malta and Alexandria telegraph. The real dispute, however, turned upon the depth and nature of the bottom in the different seas in question, and for information upon these points the Admiralty charts were referred to. These charts certainly bear out the allegation of the engineers, as was admitted by "C," that between Rangoon, Singapore, and Hong Kong a telegraph cable can be laid in a depth not exceeding 50 fathoms, which will admit of its being raised for repairs without difficulty. "C," however, insisted upon the existence of coral, and its injurious effect upon the cable; the engineers assert that, though coral exists, the cable can everywhere be laid clear of it between the reefs, and that, except in very shallow water, and where very strong currents exist, coral does not seriously injure a cable.

So much for the line to China. As regards the line to Australia, the charts show that between Singapore and Batavia the depth of the sea does not exceed 23 fathoms, and is frequently not more than 12 fathoms, which is admitted to be too shallow, though the depth of this sea is not less than that of the North Sea, where the cables connecting us with the Continent are laid. As regards the sea between the east end of Java and the head of Gulf Carpentaria, the depth, with the exception of the 550 miles which have never been sounded, varies from 40 to 80 fathoms. It is with respect to these 550 miles of sea which have not been sounded that conjecture is rife. "C" appears to be of opinion that, with the exception of 70 miles to the South of Timor, the remainder of the unsounded portion of the sea is shallow, and the engineers state that even if the 70 miles which are excepted prove to be deep, the loss in case of rupture in the cable at that point will be trifling.

As regards the practicability of the proposed telegraph, we have endeavoured to place the case as fairly and clearly before our readers as the arguments of the disputants and the evidence afforded by the charts enable us to do. It is evident that in this case we have to deal with shallow seas and short sections—two most important elements, the former especially, in the permanent success of submarine telegraphy. The Malta and Alexandria telegraph, of a length of 1,330 miles, has now worked for over three years with an average interruption of forty-five days per annum, the greater portion of which the engineer attributes to the absence of a steamer at Malta fitted up with the appliances to repair the cable when ruptured. We may, therefore, reasonably hope soon to see carried out the China and Australian lines, especially as long telegraph lines are now proved to be very remunerative, the Malta and Alexandria line having paid 17 per cent. to the Government and the lessees whilst in working order. Moreover, the Dutch and the Australian Governments have in every way encouraged the proposed lines. It is, however, a great point that their practicability has been established, and it is to this question alone that our observations have been directed.—*Money Market Review.*

POVERTY A RELATIVE TERM.—Bulwer says that poverty is only an idea, in nine cases out of ten. Some men with ten thousand pounds a year suffer more for want of means than others with three hundred. The reason is, the richer man has artificial wants. His income is ten thousand, and he suffers enough from being dunned for unpaid debts to kill a sensitive man. A man who earns five shillings a day, and does not run in debt, is the happiest of the two. Very few people who have never been rich will believe this, but it is as true as God's word. There are thousands and thousands with princely incomes who never know a moment's peace because they live above their means. There is really more happiness in the world among working people than among those who are called rich.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XIV.

A.D. 1838, April 18.—No. 7614.—Cooke, William Fothergill.—"Improvements in giving signals and sounding alarums at distant places by means of electric currents transmitted through metallic circuits." This invention may be divided into the following parts:—

Part A.—An intermediate signal apparatus that can transmit signals to either terminus as well as receive signals, being an improvement on the 5th particular of No. 7390. At the intermediate station, finger keys and a galvanic battery are connected to the intermediate apparatus, and thence suitably to the line wires, in order to communicate to stations in one direction or the other by means of a "current director," adjusted by an "index" or button on the outside of the signal apparatus. The current director consists of a wooden lever, to which wires from the keyboard are attached at the side, being insulated from each other; according as the current director is moved up or down from an intermediate position, it makes communication with fixed insulated springs, in connection with the line wires, to stations in one direction or the other, thus placing the finger keys in the circuit. When the current director is in an intermediate position (*i.e.* not in contact with either set or fixed springs), the line wire circuit is completed only through the needle coils, and signals can be received, as the communicating springs are not then pressed apart by the current director. The tail of the current director, by means of springs in a similar way, introduces the battery of the intermediate station. The signal instrument, described in connection with this part of the invention, has four needles and five line wires.

Part B.—Connecting the alarum apparatus of an intermediate station, during the time it is transmitting messages, so as to receive audible signals from stations in an opposite direction to that receiving signals from it. The current director carries a flat plate or "cross piece," at the opposite side to those connected with the keyboard, that makes connection with the opposite line wire circuit to that engaged in transmitting messages, and its return wire. The index also carries a wooden prominence, that at the same time makes contact with springs in the line wire circuit and the alarum apparatus, the wooden prominence for that purpose carrying insulated metal pieces in connection with the alarum circuit.

Part C.—Temporarily connecting a portable apparatus with the line wires to give and receive signals. At certain portions of the telegraph line the wires are carried up into boxes, and are fitted with connecting pieces that can be removed, in order to include in the circuit a battery and signal instrument when required. In connecting a portable apparatus, a block of wood, with insulated springs carrying the junction wires, is locked into the box by a cross bar passing into the notched groove used to lock its door. The signal apparatus described is only a double instrument having three line wires, and is connected up or down the line by a current director, turning half round on an axis, but on the same principles as that described in Part A. The keys described in connection with this instrument consist of small levers or finger tappets, each poised on a distinct centre pin of its own, and arranged so that the depression of the key corresponds to the deflection of the needle; this key is the same in principle as that described in No. 7390, but the application is different. Contact with the cross bar (or the continuity of the line wire) is broken by the flexure of a watch spring on the lever arm.

Part D.—Securing and protecting telegraph wires, by laying them in, or drawing them into, tubes or pipes, as gas pipes, soldered together, or screwed together with screw joints or union joints.

Part E.—Using magnetic attraction, with or without the aid of gravitation, to steady telegraph needles.

Part F.—Sounding alarums without the assistance of a local battery. The fly of a clockwork actuating the hammer is released by the deflection of a magnetic needle acting on a delicately poised lever, which has an arm that cannot resume its position until a stop on the lever is allowed to enter a notch in a slow moving wheel. The telegraph needles may be used for this purpose.

A.D. 1838, July 4.—No. 7719.—Davy, Edward.—"Improvements in apparatus for making telegraphic communications or signals by means of electric currents, parts of such apparatus being applicable to obtaining, regulating, or measuring electric currents for other purposes," consisting of:—A chemically marking telegraph. A local circuit (completed by galvanometer needles acted on by the line circuit) marks chemically prepared paper, which is moved forward by clockwork released by an electro-magnet. Two line wires are used to convey the electric current, and one return wire, with a battery and two galvanometers (deflecting opposite ways) to each wire; the battery to the return wire giving a preponderance to currents through that wire, twelve different signals can thus be produced. The action is as follows:—On one or more of six keys being pressed down, either two or three of the galvanometers act; and as the three wires admit of the current proceeding in either direction through them, it can complete either two or three out of the six circuits of the local battery; thus marking longitudinally properly prepared paper at two or three out of six places. The clock-work escapement, for moving the paper a sufficient distance between the signals, consists of two levers, one of which carries the armature, and works on a horizontal axis carried by the other lever. When the armature is attracted, it releases a pin from a notched fly vane, and enables it to move half a revolution; and when the current ceases, the pin is again removed, and replaced by lateral motion given to the second lever by a wheel pressing against a projection on it. Calico, "impregnated with hydriodate of potash and muriate of lime," is preferably used to receive the marks or signals. "Relays of metallic circuits," transmitting the electric current throughout, in the desired direction, brought into operation by means of galvanometer needles as in the above-described telegraph. An arrangement enabling the person communicating to send the communication to any desired place. Branch wires are laid to each place, and the circuit is completed to the desired place by the assistance of electro-magnets acting on a lever or levers according to the direction of the current. These magnets are charged by a local circuit, completed by galvanometers, as above. An improved galvanometer, in which the magnetic needle is mounted on a horizontal axis; the strength of an electric current is ascertained by the weight it will overcome in a scale attached to the needle, or by a sliding weight.

A.D. 1838, July 11.—No. 7729.—Callet, Louis Cyprien (*a communication*).—The title of this invention is, "Certain improvements in machinery or apparatus for producing motive power, applicable to propelling boats and other vessels, carriages, machines, and other useful purposes." This invention relates to motion obtained by means of soft iron or steel cores or "bolts," moving reciprocally within electro-magnetic "helices." This invention consists of a "bolt" or bolts attached to the extremities of a beam, similar to that of a Boulton and Watt's steam engine, and working into helices in a similar manner to that of the piston and cylinder of the steam engine, the helices being fixed to the foundation plate of the machine. Motion of the "bolts" at each extremity of the beam is produced by the galvanic current being admitted alternately to the helices at the opposite extremities of the beam; this is accomplished by means of "straps," or "thin slips or bars of copper, tin, or silver," pressing upon a "wooden cylinder or wheel" on the crank shaft, having two "pieces of silver" inserted in the wood which complete the electric circuit with each helix or set of helices alternately, and thus produce motion.

A.D. 1838, July 18.—No. 7737.—Hoe, Richard March (*a communication from Dr. H. H. Sherwood*).—This invention relates to an instrument containing a "dipping needle," with graduated vertical and horizontal arcs and tables, by which "the latitude or longitude of any place on land, or of a ship at sea, may be ascertained and determined without the aid of celestial observations, and also the dip or inclination and variation of the magnetic needle ascertained." The instrument is called, "Sherwood's magnetic geometer." The inventor states that he has constructed the above-mentioned tables from the latitude and longitude of the northern and southern magnetic poles, their rate of motion, and the position of the line of no variation at a given time, as determined by himself. Two instruments are described and shown: one, in which the dipping needle is a "rhombus," mounted upon agate centres within a vertical arc having spirit levels; it also has a horizontal arc and moveable nonius, and several moveable concentric circles of figures, so arranged as to bring the different figures required in calculation one above the other. Another, in which a "magnetized ring" is used, carrying two verniers and supported on agates; "two forked pieces of brass," that can be raised or depressed by moving a slide, place the axis of the magnet at right angles to the vertical divided circle. For observations at sea the instrument must be "suspended by universal joints," or "a liquid bath." The moveable concentric circles of figures consist of 9 circles nearest the centre of the

instrument, containing "a table of one-half the diurnal variation in every latitude;" next to these, 6 circles, containing a table of "the declination of the needle from nothing to its maximum of 23° 28′ at the terrestrial equator;" and externally, next to the nonius circle, 6 other circles giving "the declinaton of the magnetic axis, or line of no variation, in which "the declination of the needle from nothing to 90° is converted into degrees of longitude." Copious examples are given of the obtainment of the variation of the needle, and latitude and longitude of places, from the instrument and table, but there is no special explanation of the precise method of working them.

A.D. 1838, July 24.—No. 7742.—Elkington, George Richards, and Barratt, Oglethorpe Wakelin.—"Improvements in covering and coating certain metals," in which improvements electric force is used. To coat copper and brass with zinc, "to prevent oxydation:"—"Zinc in the state of powder or pieces" is added to dilute muriatic acid, and allowed to remain "until the acid and zinc cease to act upon each other;" this solution is then poured off and boiled with comminuted zinc, during which time the articles to be coated are immersed in the solution, and brought into "contact with the metallic zinc," when they speedily become coated, and are then removed, washed, and dried. To coat iron and steel with the above solution:—The articles are previously coated with copper, by cleansing them in dilute sulphuric acid, and immersing them in a solution of sulphate or nitrate of copper, whence they are speedily removed and washed; or they may be at once immersed in the muriatic acid solution in contact with the excess of zinc, removed, washed, and dried. In either of the above processes the copper surface may be "introduced into a dilute solution of nitrate of mercury, and then again boiled in the solution of zinc," by which the same object is obtained. "Iron, steel, copper, brass, &c.," are coated with an "amalgam of zinc" "to prevent oxydation," by immersion in contact with the amalgam to which dilute acid has been added. Muriate or sulphate of ammonia, or the oxides of the metals, may be employed instead of muriatic acid, or other acids may be used; or the amalgam of zinc may be employed "in a melted state." Coating by fusion may be employed in conjunction with the above processes. Iron or steel is coloured to imitate brass, by coppering and zincing it as above described, and submitting it to heat in a closed oven until the required colour is obtained, as in "semiloring" copper and brass. [Although no mention is made of electricity in the specification, the immersion of the metal in the solution of zinc in contact with zinc or amalgam of zinc, forms a galvanic circuit, and thus employs electric force.]

A.D. 1839, June 8.—No. 8096.—De Bode, Baron Henry.—"Improvements in the means of rendering magnetic needles less prejudicially influenced by local attraction, which improvements are applicable to other magnetic objects for the same purposes." A mariners' compass is described and shown, in which the needle and card are supported by a pivot cemented to "a double glass vessel," containing "quicksilver," so as to get "a metallic surface of quicksilver within two surfaces of glass between the magnetic needle and the local quantity of iron." This glass vessel "is placed within an outer vessel of lead, consisting of two thicknesses of lead, which is a metal little affected by the attractions or fluids which influence the magnetic needle, and there is, by preference, a thickness of glass between the double lead vessel." "The compound vessel containing the compass is suspended on the ordinary gimbles" by means of "a brass strap." A concave glass forms a "corner" [cover?] to the vessel, thus allowing "more play to the card," but preventing "its being thrown off the point." A chronometer may be placed in such a vessel, to prevent "the errors which have been found to be produced by magnetic influences."

A.D. 1839, August 26.—No, 8207.—Pinkus, Henry.—Methods of applying and using the power derived from the pressure of the atmosphere, by means of a partial vacuum called the "pneumatic atmospheric auxiliary power," and the impelling force to be derived from "explosive mixtures" (carburetted hydrogen gas in union with air) called the "gaso-pneumatic power." The specification and drawings describe and show, at great length, the following particulars:—A method of applying the above motive powers to the various operations of agriculture, by means of "hermetically sealed mains or pipes" laid down in the fields, which, in the first case, are exhausted of air by a stationary engine, and, in the second case, conduct gas from the stations to the various parts in which the power may be required. A locomotive "atmospheric impelling engine," and a locomotive "gaso-pneumatic engine" connected to the mains by flexible tubes. Various agricultural implements connected with the "impelling engine," ploughshares attached to levers, harrows, scythes, and spades. In the application of the invention to railways, canals, and common roads, "close tubes" are laid down, which are connected at certain distances with "valve mains," having longitudinal valves formed by metal valve plates pressing together, and placed angularly on the main over a longitudinal aperture, so as to admit a "flat pipe or tongue" between them from the locomotive. A valve may be made by having one valve plate of leather strengthened with copper plates, whose upper edge lays in a groove in a "raised vertical surface;" the groove contains an insulated copper wire, which is included in a galvanic circuit by a "conductor" projecting from the locomotive, thus melting cocoa-nut oil in the groove, as the train passes, "in advance of the locomotive;" the galvanic batteries may either be on the locomotive or at stations along the line, in which case a wire is laid parallel to the gas valve main; this last valve may extend the whole length of the railway. "The pneumatic principle may be applied" to agricultural purposes by means of "a plenum instead of a partial vacuum."

A.D. 1839, October 24.—No. 8248—Graydon, George.—The title of this invention is, "Certain improvements in instruments for which Letters Patent were formerly granted to me, and which were called therein, 'A new compass for navigation and other purposes,' part of which improvements are applicable to instruments for measuring angles at sea or on shore by aid of reflection or refraction, or of reflection combined with refraction, and part are applicable to magnetic compasses for ascertaining true bearings from celestial observations, and for comparing the same with the bearings of the magnetic needle contained in such compasses, whereby to determine and be enabled to allow for the deviation of such needle from the true meridian, whether by variation, local attraction, or other cause of error;" but it only refers to magnetic compass needles and cards as a part of the "celestial compass" alluded to in this specification. For the former invention alluded to, see Letters Patent, No. 4996. "The compass bowl," "carrying the measuring circles of the celestial compass," has a pendulous weight, and is suspended on "a series of gimbal rings" (three are shown in the drawings), with weights attached to them, so as to act as pendulums of different lengths, and thereby prevent the motions of one from being communicated to the others, and keep the instrument horizontal. In another modification of the invention, the weighted compass bowl is mounted on the vertex of a weighted cone, which is on the vertex of another weighted cone, on a central pivot; the weights being so disposed as to act as in the gimbal compass first described. A method of ascertaining the variation of the magnetic needle by this instrument is set forth. "An instrument for measuring angles by reflection, after the mode of Hadley's sextant, but instead of referring those angles to the visible horizon of the sea by directing the telescope," "or line of sight to view that horizon, the same is directed to view the pole star," is also described and shown.

A.D. 1839, November 2—No. 8255.—Taylor, William Hannis.—"Improvements in obtaining power by means of electro-magnetism." The specification and drawings describe and show rotary engines, in which either the "armatures" are fixed, and the electro-magnets revolve, or *vice versâ*, these being arranged in the circumference of a circle, so that the magnets or "armatures" (as the case may be) may freely move near to the "armatures" or magnets opposite to them. The magnets are demagnetised when opposite each armature, and until within the attractive influence of the next armature, thus producing a continuous rotary motion. A conducting disc, inlaid with non-conducting material, and in connection with one pole of the galvanic battery, magnetises and demagnetises the electro-magnets at the proper times; and by arranging the conductor in connection with the disc communicating with the electro-magnets, and thence with the other pole of the battery, in different relative positions, the engine may either move in a forward direction, be stopped, or reversed. No change of magnetic polarity takes place in this engine.

TELEGRAPHY AND PHRENOLOGY.—In these days of rapid transmission of news, young men often apply to us (Editors of *American Phrenological Journal*) to know what organs of the brain are most necessary to a telegraph operator. In reply to this, we say in general, all the intellectual faculties well developed and active, are very desirable for this as for any other intellectual pursuit; but the telegraph operator needs large perceptive organs, especially Individuality, Order, and Time; and if Time be well developed, so much the better, as this gives a ready discrimination of sounds, aiding him to read by the "click" of the instrument. Of course the temperament should be favourable to patient attention and studious habits

MEETING OF THE BRITISH ASSOCIATION AT BATH.

The valuable experiments made by Mr. Glaisher, under the direction of the Scientific Balloon Committee, reveal a number of interesting facts concerning atmospheric electricity and magnetism. In the report of this committee, read by Colonel Sykes, M.P., supplemented by a very interesting narrative of aerial experiments by Mr. Glaisher, our readers will find a considerable amount of useful information. It is not in our power to publish the documents in their entirety, but the following abstracts will be found to contain the pith of the papers:—

Colonel Sykes, M.P., said, the Balloon Committee have sanctioned the following ascents, nine in number, since the appointment of the committee at Newcastle, August 31, 1863, viz.:—from Newcastle, September 29th, 1863; from Wolverhampton, October 9th, 1863; from the Crystal Palace, near London, January 12th, 1864; from Woolwich, April 6th, 1864; from Woolwich, June 13th, 1864; from the Crystal Palace, June 20th, 1864; from Derby, June 27th, 1864; from the Crystal Palace, August 28th, 1864. It is the desire of the committee that winter ascents should be made in the months in which heretofore they had not hitherto been able to effect them; and now, except in three months, they had the results of ascents made in all the months of the year. Owing to the destruction of Mr. Coxwell's great balloon, at Leicester, four of the above only were high ascents. In the other ascents, Mr. Glaisher obtained a seat in the car of the balloon, and space for room of the important instruments, at a cost of £5 for each ascent. These ascents were made by Mr. Coxwell on public occasions, and to a moderate height only, varying from one to three miles. Mr. Glaisher, with unabated zeal and fearlessness, made the ascents, and the necessary observations, the details of which accompany this report. The committee was instructed to "examine the electrical condition of the atmosphere at different heights, and to verify the law of decrease of temperature obtained by Mr. Glaisher, and to compare the contents obtained in different states of the atmosphere." Mr. Glaisher will explain the difficulties in carrying out the first instructions, and the necessity for renewed attempts to verify the electrical condition of the atmosphere. The second instruction has been fully carried out. Owing to the high ascent, ordered to take place at Wolverhampton, in July, 1863, and for which gas was prepared and observed, but which was protracted by continued bad weather, and only taking place on the 29th September, the account of the expenditure from the grant of 1862-3, could not be submitted at the meeting at Newcastle. The account has now been transmitted to the treasurer, with the necessary vouchers, and the disbursements amounted to £199 19s. 9d., out of the £200 granted. The account, with the disbursements, from the grant of 1864, cannot be submitted at the present meeting, owing to some outstanding bills which have not yet come to hand. The electrical and magnetic conditions of the atmosphere at high elevations being incomplete, and an important question with respect to atmospheric refraction having arisen, the committee recommend that further researches be made into these subjects, that the committee be re-appointed, and that £150 be placed at the disposal of the committee. The gallant colonel added, that he could not conclude this report without calling upon the Association generally to express its gratitude to Mr. Glaisher for his perseverance and zeal in carrying out these experiments at great expense to himself, for although the Association defrayed the cost of the actual ascents, the hotel expenses, and other similar charges, he had to defray out of his own pocket.

Mr. Glaisher, who was received with considerable cheering, read the following paper:—The Committee of the balloon experiments was appointed last year to examine the electrical condition of the air at different heights—to verify the law of the decrease of temperature, and to compare the constants in different states of the atmosphere. As to the first object, no progress was made in the beginning of the year, except preparing an instrument for the investigation, under the superintendence of Mr. Fleeming Jenkin, but as no flame or fire of any kind can be admitted in the car of the balloon, for fear of igniting the gas, the instrument could not be used, it has been altered to be employed with water, but is not yet in a fit state for observation. It happens unfortunately that electrical instruments necessitate the use of a constant flow of water, and occasionally of two streams at the same time just below the car of the balloon. The committee felt the presence of such water near the instruments might exercise considerable influence on the instruments, by moistening the atmosphere, and thus throw considerable doubt on some of the experiments, particularly on those as to the humidity of the atmosphere—a primary object of research. With respect to the second object, viz., verifying the law of the decrease of temperature in different states of the atmosphere—it is desirable to obtain as many observations as possible at times in the day and year, at which the experiments had not previously been made, to determine whether the laws would hold good at one time in the year, and at others. The committee at all times pressed on me the importance of magnetic observations in the higher regions; the Astronomer-Royal suggesting the use of a horizontal magnet, and taking the time of its vibration at different elevations, a method seldom practical, as the balloon is almost always in a state of revolution. Dr. Lloyd suggested the use of a dipping needle, placed horizontally when on the ground, by means of a magnet alone, and so that when in the balloon the deviation from horizontality might be noticed, which deviation would be independent of the revolving motion of the balloon. This I have been unable to attempt at present. I readily assented to the wish of the committee, as expressed at Newcastle, that I should not ascend more than four or five miles, as I had found that all observations above five miles would be inferred from those below five miles. And, moreover, the balloon, after so many rough descents, had become, in Mr. Coxwell's opinion, too unsafe for extreme high ascents, I have, therefore, no report to give of any extreme high elevation attained during the past year, yet new facts and new physical conditions have become known in some of the nine ascents upon which I have to speak. Mr. Glaisher then gave accounts of his nine ascents. After the ascent of the 29th September, Mr. Coxwell condemned the balloon as unsafe, and determined to build another, capable of containing 10,000 cubic feet more than the old one, to carry two observers the height of five miles. This needed trying in low ascents, till it proved perfectly gas-tight, there always being a leakage through the new material, and, after several trial trips, it was made and rendered gas-tight, and was destroyed at Leicester. One would scarcely believe it possible that such an act could take place in the centre of England in the present day, but it was so destroyed as to put a stop to all pre-arranged experiments. The Mayor of Leicester has recently presided over a meeting for the purpose of raising a subscription to assist Mr. Coxwell to rebuild a new balloon, which I hope will help to remove the stigma now resting upon Leicester (cheers). I trust the Foresters will also help to remove the stain now resting upon them; for if the act was not that of the Foresters, it was at one of their gatherings, under their superintendence, and the destruction of the balloon by force, I can learn, was not attempted to be stopped by them. He then described the ascent from the Crystal Palace. Having alluded to his observations as to the lines in the solar spectrum, he proceeded to say it was very clear, from the particulars of each ascent, that they cannot all be combined for deducing general laws. Those ascents, which have been made during the past year, under similar circumstances, to those from which the law of decrease of temperature were found when combined, do not change the values previously priced to any great amount, but those which have been made under other circumstances, such as in that in the winter, and at times of the setting sun, differ very greatly indeed. The deviation of this law, however, in winter, is certainly of the highest importance to us. The meeting with a strong current of air S.W., is as great in thickness as nearly a mile, sweeping over our country in the season of winter, and which, one current I know, continued many days, may be the cause of the much higher temperature we enjoy than that due to our position on the earth's surface. This high temperature has been attributed to the Gulf stream, but this washes the coast of France as it surrounds our own coasts, and yet France does not enjoy to the same degree our warm winters. Norway, likewise, enjoys with us a similar warm winter; and it would seem from the observations in January that very much of the comfort of our winters is owing to the south-west wind passing uninterruptedly over the sea to us. These views were published by Dr. Black, of Edinburgh, and seem to be confirmed by the warmth met with in the north-west current I passed through. I have taken meteorological observations since, in fact, the year 1829, and for twenty years I have received at the end of every month the observations made over the whole of this country from forty to fifty years. These he had reduced and discussed, and laid the results down in curves, so that they may be seen; yet I am unable to tell the weather a week hence. I have made and discussed more observations than any other observer, and all I can do is to speak generally of the probable state of the weather for one or two days in advance. Owing to its insular situation, and its variation of climate, this is not the best country for taking observations; and I am glad to learn that similar observations are about to be made in France, and I trust they will be made in those countries where the weather is more uniform, and the observer can be at ease for hours out of sight of the earth. In France, Messrs. Bixio and Barrac made a scientific ascent in July, 1850, from Paris, and passed through a cloud composed of oxides which sustained themselves in the air, as it appeared to them, contrary to the laws of gravity, and upon their horizontal surfaces there was beneath the horizon an exact image of the sun, formed by the reflection of the luminous rays on the crystal: the temperature of the cloud was minus 40°. Many ascents must, therefore, be made before any general laws can be laid down. I think the law of decrease of temperature, under ordinary circumstances, both with a cloudy sky and a clear sky, show the snow is above the horizon in summer and adjacent months. I think it is pretty well determined, but from the only series of observations made in winter, we cannot say such laws hold good throughout the year, nor can we say the same laws will hold good day and night. When I undertook to make these experiments, I expected that a few ascents would have been all that would have been required of me. I have made no less than twenty-two, and so far from exhausting the subject, they indicate a much wider field for future operations. In carrying out these experiments, and the work connected with them, I have given up all my leisure time freely; Mr. Coxwell has done the same, in the most unselfish manner—indeed, I may say, that had it not been for him, the generous spirit in which he has entered into these experiments, they never could have been made, except at a multiple of their present cost. Mr. Glaisher was cheered frequently during his address, which he illustrated by diagrams. Mr. Glaisher resumed his seat amidst enthusiastic applause.

Mr. President was sure that he might, on behalf of the Section, thank Mr. Glaisher most cordially for the very interesting account he had given, and express their hope that he might go on making the series of ascents which were necessary to complete his unexampled and most valuable

experiments and investigations, with the same success and pleasure to himself as had attended his previous experiments.

Mr. Fleeming Jenkin observed that, as Mr. Glaisher had been kind enough to mention his name, in terms far more complimentary than he deserved, as to the assistance he had been enabled to render in carrying out these electrical experiments, he desired only to say that he was ready, at any expense of time and trouble, to aid, so far as he could, in completing those experiments. Mr. Glaisher had referred to the danger incurred in the use of the existing instruments. As those instruments were now arranged, he believed they were safe, provided no mistakes were made in using them, in the same way that guns were safe, if used with proper care, and no mistakes were made by those into whose hands they fell; but in all electrical experiments made in the higher regions, where electrical disturbance was always going on, and especially in the presence of so large a volume of gas, he found there must always be more danger. He was quite satisfied that Mr. Glaisher would not on that account be deterred from continuing his observations. He was happy to add that he, Mr. Jenkin, was to have the aid of Mr. Varley in the attempt to determine what the conditions were that should reduce that danger to a reminiscence.

DAVY AND THE NITROUS OXIDE.

The dangers which enthusiastic men of science will voluntarily undergo for the sake of testing new principles have never been more strikingly exemplified than in the history of Sir Humphrey Davy's early experiments on the effect of nitrous oxide, popularly known as "laughing gas." Davy began his chemical studies in March, 1798, when a youth of eighteen, and only two years later appeared his "Researches," which immediately gave him high rank, not as a mere chemist, but as an original discoverer. Herein, for the first time, the properties of nitrous oxide, and the wonderful effects of that gas in respiration, were disclosed to the astonishment of the public. Hitherto it had been regarded among natural philosophers with a sort of vague horror, and from its deadly effects upon small animals it was suspected that it was the very principles of the plague itself—that terrible visitation which, from time to time, swept over Europe. Nothing daunted by this, the young philosopher boldly resolved to try its effects upon his own system. He could not have been ignorant of the terrors of Spallanzani's experiments upon the gastric juice, and only a short time before the brave Pelletier, the French chemist, had lost his life in the attempt to breathe another kind of poisonous gas. But the boy philosopher thought it necessary to compare the effects of nitrous oxide with those of common stimulants, and he was resolved to pluck knowledge out of this dangerous trial. With this view he shut himself up, and first submitted himself to intoxication so extreme as to produce distressing and even alarming symptoms. To ascertain the effects of an atmosphere containing large quantities of the same gas, he enclosed himself in a box, and at three successive intervals, for an hour and a quarter (during which time he remained in the box), and sixty quarts of the gas thrown in, finally constituting a large proportion of the air which he was breathing. When the last twenty quarts were thrown in, his emotions became similar to those produced by a moderate dose of the pure gas; but, not satisfied with this, immediately after coming out of his cage, he began to breathe in twenty quarts of nitrous oxide, probably the most effectual trial ever made of this wonderful agent.

In his own account of this audacious experiment, Davy observes:—"A thrilling, extending from the chest to the extremities, was almost immediately produced. I felt a sense of tangible extension highly pleasurable in every limb; my visible impressions were dazzling and apparently magnified; I heard distinctly every sound in the room, and was perfetly aware of my situation. By degrees, as the pleasurable sensation increased, I lost all connection with external things; trains of vivid, visible images rapidly passed through my mind, and were connected with words in such a manner as to produce perceptions perfectly novel. I existed in a world of newly connected and newly modified ideas. I theorized; I imagined that I made discoveries. When I was awakened from this semi-delirious trance by Dr. Kinglake, who took the bag from my mouth, indignation and pride were the first feelings produced by the sight of the persons about me. My emotions were enthusiastic and sublime, and for a minute I walked round the room, perfectly regardless of what was said to me. As I recovered my former state of mind, I felt an inclination to communicate the discoveries I had made during the experiment. I endeavoured to recall the ideas; they were feeble and indistinct. One collection of terms, however, presented itself, and with the most intense belief and prophetic manner I exclaimed to Dr. Kinglake, 'Nothing exists but thoughts!—the universe is composed of impressions, ideas, pleasures, and pains.'"

The impunity with which Davy had passed through these wonderful trials emboldened him to attempt the breathing of the deadly fumes from charcoal. His first attempt was made upon four quarts of carburetted hydrogen gas, of which he made three inspirations. "The first inspiration" (he tells us) "produced a sort of numbness and loss of feeling in the chest and about the pectoral muscles. After the second inspiration I lost all power of perceiving external things, and had no distinct sensation except a terrible oppression on the chest. During the third inspiration this feeling disappeared; I seemed sinking into annihilation, and had just power enough to drop the mouthpiece from my unclosed lips. A short interval must have passed during which I respired common air before the objects about me were distinguishable." On recollecting himself he faintly articulated, "I do not think I shall die." Putting one finger on his wrist, he found his pulse thread-like, and beating with excessive quickness. Extreme giddiness, loss of memory, and numbness, succeeded, with excruciating pains in the forehead and between the eyes, and transient pains in the chest and extremities.

Davy was, as far as his philosophical learning went, entirely self-instructed. He was born at Penzance, in Cornwall, on the 17th of December, 1778. Though some attempt has been made to conceal the fact, there is no doubt that his father, Robert Davy, followed the humble occupation of a wood-carver. Robert was known in that town as "little carver Davy," and his son (Humphrey), when young, was always spoken of there as "carver Davy's boy." His father dying when the lad was only sixteen, his mother commenced the business of a milliner, and apprenticed her child to an apothecary at Penzance, where, for the first time, he began to show an interest in his favourite study.

"His means, of course," says his brother, Dr. Davy, "were very limited; not more extensive than those with which Priestly and Scheele begun their labours in the same fruitful field. His apparatus consisted chiefly of phials, wine-glasses, teacups, tobacco-pipes, and earthen crucibles, and his materials were generally the mineral acids and the alkalies, and some other articles which are in common use in medicine." He began his experimental trials in his bed-room, in a friend's house, in which he was a favourite inmate. Here there was no fire, and when he required it he was obliged to come down to the kitchen with his crucible. His biographer, Dr. Paris, states that Davy was indebted to the accident of a wreck on the coast for a case of surgical instruments. This included a clumsy clyster apparatus, which he turned into an air-pump. The sacred vessels and professional instruments of the surgery were, without the least hesitation, put into requisition for any chemical experiments.

It can hardly be doubted that Sir Humphrey Davy's constitution, which was so vigorous in youth, withered and decayed long before he had reached old age from the effects of injuries sustained by these early experiments. He died in 1829, at Geneva, of an attack of apoplexy, but his end was singularly peaceful. When his brother (Dr. Davy) entered the room, Sir Humphrey said: "I am dying! When it is all over, I desire that no disturbance of any kind may be made in the house. Lock the door, and let every one retire quietly to his apartment." The mortal remains of the wood-carver's son—the great philosopher and discoverer—were honoured with a public funeral, and deposited in the cemetery outside of the walls of Geneva.—*American Artizan.*

TELEGRAPHIC NEWS.

Collision at Sea.—The Dix Décembre, Commander Chevalier, French Government telegraph steamship, in the Gulf of Lyons, on Tuesday, the 18th ult., came into collision with the Sea-dog, a new schooner, 123 tons register, from Marseilles. The Sea-dog was sunk, and the captain (Mr. Peters), the boatswain (Thomas Martin), and a sailor (name unknown), were drowned. The captain of the Dix Décembre perceived the Sea-dog approaching, and endeavoured to put his ship about; but the movement was too late, and the Sea-dog was stricken amidships and cut in half. Four of the crew were saved.

Stefani's Telegraph.—The *Malta Observer* of the 20th ult., says:—"Some surprise is expressed, and with an appearance of reason, at the non-receipt of a telegram from Stefani since the 5th inst. We think that this delay may be accounted for by the fact that no event of great political importance has passed on the European Continent within the last fortnight, and that Stefani is allowed to exercise a certain discretion in the transmission of telegrams. In a week there may be occasion to forward several telegrams." This line of communication has long been remunerative to its proprietor; we hope that the manner in which our contemporary accounts for the non-receipt of telegrams may prove accurate.

Cape Clear Telegraph Station.—The *Cork Reporter* states that this station, which has been open a little over twelve months, is, for the present, closed, as far as intercepting American steamers is concerned, the South-Western of Ireland, at Crookhaven, and the Magnetic offices having amalgamated. The Cape will, however, be kept open for meteorological purposes, and will, in all probability, be open again in a few months for the intercepting of steamers. The Flying Childers left for Cork on Tuesday, and is to be transferred to Roche's Point, where the Magnetic Company are about to establish a new station. It is now to be hoped that Skibbereen will be connected with Crookhaven forthwith. The expenses of so doing will be little or nothing, as the wires already, we may say, pass through the town. The advantages of connecting these two places by instantaneous communication are various and quite apparent. Skibbereen, the Queen City of the West, supplies Crookhaven with almost all the necessaries of life; the custom-house, with which Crookhaven must of necessity transact considerable business, is situated in this town, and frequently captains of vessels have to travel a distance of thirty miles, which in many instances could be avoided, were the two places connected by telegraph. This want has long existed, and much disappointment was felt on the opening of the Crookhaven line at the non-establishmet of an office here. Therefore it is that we hope provision has now been made for establishing communication throughout the entire line.

Electric Telegraph Company.—Damaging the Telegraph.—Charles Jones, Frederic Morton, and William Graham, were convicted at Bicester on the 16th of September, 1864, of having, on the 22nd August last, broken one of the insulators of the telegraph line by pelting at it with stones. Jones was sentenced to six weeks' imprisonment; Morton to a fine of £1 or fourteen days' imprisonment; and Graham to a fine of 10s. or seven days' imprisonment. Similar cases of wilful damage having occurred in other districts, the Electric Telegraph Company have given notice that a reward of £5 will be given to any person or persons who shall give information which shall lead to the conviction of any offender or offenders who shall be detected in any way injuring the Company's property.

Dangerous Telegraph Wires.—A correspondent, signing himself "One of the Public," writes to the *Times* on the above subject; the letter is not very perspicuous, but should receive consideration:—"I venture, through you, to draw the attention of the United Telegraph Company (?) to the great necessity of having their wires firmly and securely fastened to those places wherever they may be allowed to carry them across our turnpike roads. As an instance of the danger to which the public are exposed in the event of such precaution being neglected, I may mention that a few days since my coachman's hat was nearly knocked off by one of the company's wires, which, having slipped from the cap on the top of one of the telegraph posts, was hanging across the road. [what road?] Fortunately this displacement of the wire took place in broad daylight; but had it happened at night instead, the affair would have been much more serious, &c."

Electric Telegraphy in Scotland.—At the meeting of the Town Council of Edinburgh on Tuesday, October 25th, the Town Clerk laid on the table a report from the Lord Provost's Committee, under the remit to them to consider and report as to the expediency of connecting the various police-stations with the head office by means of the electric telegraph. After giving the matter all the attention in their power, the Committee recommended the establishment of this communication, the adoption of Siemens, Halske, & Co.'s instruments for that purpose, and suggested that it be remitted to the Lord Provost's Committee to have their resolution carried into effect. The Lord Provost said that in many places the electric telegraph between the various police-stations had been the means of saving property from fire, as well as of detecting crime. The report was approved of.

MISCELLANEA.

Mixture of Sulphuric and Nitric Acids a Solvent of Gold.—A. Reynolds writes to the *Chemical News*, "While examining an alloy of silver and gold for the purpose of ascertaining the percentage of gold that it contained, I found to my surprise, that a mixture of sulphuric acid and nitric acid dissolves gold to a considerable extent. This fact seemed to be of some importance, and being unaware of a similar observation having been hitherto made, I send you a note of it."

On the Respiration of Flowers.—M. Cahours, in a note to the French Academy of Sciences, says, that while the green parts of plants, under the influence of light, absorb carbonic acid, assimilate the carbon, and give out oxygen, the coloured parts, on the contrary, under the same circumstances, absorb oxygen and give out carbonic acid. The amount of carbonic acid evolved seemed to increase as the temperature rose; and a growing flower gave out more than a fully blown one.

The Submarine Cables of the World.—No fewer than 52 lines of submarine telegraph cable have been laid by English firms in different parts of the world, all of which are in successful operation, with the exception of that between France and Algiers, and it is supposed that was injured by lightning. The longest line in operation is that between Malta and Alexandria, 1,535 miles. The deepest water in which any working-cable rests is 1,550 fathoms—1.45 miles—between Toulon and Corsica. The aggregate length of working lines given in the table is 5,105 miles, and this does not include a number of short lines laid in different parts of the world, nor those laid by Felten & Guilleaume, of Cologne, amounting to more than 1,000 miles. One line has been laid 13 years, five have been laid 11 years, four 10 years, and others shorter periods. This estimate does not include the cable lately laid in the Persian Gulf.

The Terrible Effects of Lightning.—Dr. Chretien, of Montpellier, has sent an account to the Academy of Sciences of a remarkable instance of the terrible effects of lightning. On the 2nd ult., he was sent for to ascertain the death of a youth of sixteen, killed instantaneously by the electric fluid in his bed, he being ill at the time. His mother and three young men who had come to see him were in the room when the catastrophe occurred. One of the young men was seated at the foot of the bed, another near the bolster, and the third close to the door of the apartment, which was on the first floor, contiguous to the roof of the house; the mother was between the second and third visitors. The lightning penetrated into the house through the wall of a large room adjoining the sick room; it broke all the window panes in the former before reaching the other where the company were. The young man at the foot of the bed had the legs of his trousers partially burnt off; the second received a wound on one of his legs, and the mother had her left leg cruelly bruised, the stocking was partially burnt, and indeed burns were perceptible on the flesh. Her son, as already stated, was killed, and the fluid ultimately escaped through the window.

Scientific Meeting.—A congress of mathematicians from almost all the states of Europe met in Berlin, on the 15th ult., to make arrangements for re-measuring degrees of longitude in Central Europe.

Heat and Force.—Whenever friction is overcome, heat is produced; and the amount of heat so produced is the exact measure of the force expended in overcoming the friction. Professor Tyndal says, while speaking upon the subject of "Heat Considered as a Mode of Motion:"—"We usually put oil upon the surface of a hone; we grease the saw, and are careful to lubricate the axles of our railway-carriages What are we really doing in these cases? Let us get general notions first; we shall come to particulars afterwards. It is the object of the railway engineer to urge his train boldly from one place to another. He wishes to apply the force of his steam or his furnace, which gives tension to the steam to this particular purpose. It is not his interest to allow any portion of that force to be converted into another form of force which would not further the attainment of his object. He does not want his axles heated, and thence he avoids as much as possible expending his power in heating them. In fact he has obtained his force from heat, and it is not his object to reconvert the force thus obtained into its primitive form. For by every degree of temperature generated by the friction of his axle, a definite amount would be withdrawn from the urging force of his engine. There is no force lost absolutely. Could we gather up all the heat generated by the friction, and could we apply it mechanically, we should by it be able to impart to the train the precise amount of speed which it lost by the friction. Thus every one of those railway porters whom you see moving about with his can of yellow grease, and opening the little boxes which surround the carriage axles, is, without knowing it, illustrating a principle which forms the very solder of Nature. In so doing he is unconsciously affirming both the convertibility and the indestructibility of force. He is practically asserting that mechanical energy may be converted into heat, and that when so converted it cannot still exist as mechanical energy, but that for every degree of heat developed, a strict and proportional equivalent of locomotive force of the engine disappears. A station is approached say at the rate of thirty or forty miles an hour; the brake is applied, and smoke and sparks issue from the wheel on which it presses. The train is brought to rest: how? Simply by converting the entire moving force which it possessed at the moment the brake was applied, into heat."

Reducing Aluminium by Zinc.—*Le Genie Industriel* contains the following description of a new process for obtaining aluminium, recently patented by M. N. Basset, chemist, of Paris. If the statements are correct they are of great value:—"The alkaline metals have been erroneously regarded heretofore as the only reducers of the chloride of aluminium, double or single, and this error has contributed to maintain this new metal at its elevated price. All of the metaloids and the metals which form, by double decomposition, protochlorides or sesquichlorides, more fusible or more volatile than the double chloride of aluminium, may operate the reduction of the salt, as well as of the single chloride; thus, arsenic, boran, cyanagen, zinc, antimony, mercury, and even tin, the amalgams of zinc, of antimony, and of tin, may be employed to reduce the chloride of aluminium single or double. The author intends to apply the legal privilege accorded by his demand for a patent to this general principle as well as to the particular application which follows. He employs zinc by preference in consequence of its low price, of the facility of its employment, of its volatility, and of the property which it presents of metalizing easily the aluminium in measure as it is set free. When there is put in presence of the double chloride of aluminium with zinc [we translate literally] at the temperature of 250° to 300° (centigrade) there is formed chloride of zinc and free aluminium. This dissolves in the zinc in excess, and the chloride of zinc, combining with the chloride of sodium, the mass becomes little by little pasty, then solid, while the alloy remains fluid. If the temperature is raised the mass melts anew; the zinc reduces a new proportion of chloride, and the excess of zinc enriches itself proportionally. These facts constitute the base of the following general process. One equivalent of the chloride of aluminium is melted, and when the vapours of hydrochloric acid are dissipated four equivalents of zinc, in powder or in grain, is introduced. The zinc melts rapidly, and by agitation the mass of the chloride thickens and solidifies. This is the first operation. This mass composed of chloride of aluminium, chloride of sodium, and chloride of zinc, is piled in a crucible or in a furnace and the fluid alloy (*l'alliage coule*) is placed above. The heat is gradually raised to a bright red, and this temperature is maintained for an hour. The melted mass is stirred with a rake, and poured out. It is an alloy of aluminium and zinc in pretty nearly equal proportions. This is the second operation. This alloy melted on some chloride which has been subjected to the first operation, furnishes aluminium containing only a small per cent. of zinc, which disappears by a new fusion under the chloride mingled with a little fluoride, provided the temperature is raised to a white heat and maintained till the cessation of the vapours of zinc, in the absence of air. The aluminium obtained is pure if the zinc employed contains no foreign metals. It suffices to remelt it to cast it into ingots. In case the zinc contains iron, or even if the chloride of aluminium holds a portion of that metal, the metallic product of the second operation may be treated with dilute sulphuric acid. The insoluble residue is washed and melted, layer by layer, with fluoride of calcium or cryolite, and a small quantity of double chloride, destined solely to favour the fusion. The principles and the method which precede, constitute according to the author, a new and economical manufacture of aluminium.

THE APPLICATION OF ELECTRICITY TO GAS ENGINES.—Mr. S. L. Weigand, of Philadelphia, has recently effected some improvements in gas engines which are thus set forth in his specification, an abridgement of which has been published by the American Commissioners of Patents:—First, I claim protecting the piston, or its equivalent, from deposits of residuum in the cylinder by means of a fluid of greater specific gravity than the residuum. Second, combining the conducting electrical points or circuit closing apparatus with the valve gear so that the circuit is closed after closing the valve. Third, combining the regulator with the induction valves so as to regulate the duration of flow of gas and air or other explosive mixture to the cylinder, or its equivalent, by the velocity of the engine, and thus to control the velocity of the engine. Fourth, the induction valves, when constructed and used substantially as described. Fifth, the eduction valves, when constructed and used substantially as described. Sixth, imparting motion to the valves by means of the coupling shafts, in the manner herein-before set forth and described."

A NEW HYDRO-CARBON IN THE COAL-TAR SERIES.—M. A. Bechamp recently announced to the French Academy of Sciences the discovery of a new hydro-carbon in the mixture that makes up coal-tar. In rectifying with care the products which boil between 130° and 150° cent. (266° and 302° Fah.) M. Bechamp observed that the thermometer remained a long time stationary in the neighbourhood of 140° (cent.), a temperature midway between the boiling points of xylole and cumole. Keeping this temperature constant, he separated from 30 measures of brown tar, one measure of a liquid hydro-carbon. A new rectification allowed the whole of this to pass between 139° and 140°. This constancy of the boiling point forbids the supposition that it is a mixture of xylole and cumole. By further purification with concentrated sulphuric acid and sodium the author finally succeeded in producing in the neighbourhood of 900 cubic centimetres of a product boiling from the commencement to the end at a temperature between 139° and 140° (282° and 284° Fah.)—*Le Genie Industriel.*

SIR W. SNOW HARRIS ON THE LAWS OF ELECTRICAL FORCE.—Sir W. Snow Harris, whose researches led eventually to the protection of ships from lightning by the use of conductors, has laid before the Royal Society "further inquiries on the laws and operation of electrical force." He refers to the experiments of Le Monnier, Cavendish, and Volta, as showing that bodies do not take up electricity in proportion to their surfaces; and to the opinion of Volta, that a plain surface extended in length sustains a greater charge, and that this is attributable to the electrical particles being further apart upon the elongated surface, and consequently further without each other's influence. Sir Snow Harris endeavours to show that by extending a surface in length we expose it to a larger amount of inductive action from surrounding matter. No very satisfactory experiments seem to have been instituted, showing the relation of quantity to surface. On a further investigation, the laws of electrical charge, the quantity which any plain rectangular surface can receive under a given intensity, is found to depend not only upon the surface, but also on its linear boundary extension. Hence the charge of the rectangle is much greater than that of the square, although the surfaces are equal, or nearly so. It is from a rigid experimental examination of this question that electrical charge depends upon surface and linear extension conjointly. Every plain surface seems to have what may be termed an electrical boundary, having an important relation to the grouping or disposition of the electrical particles in regard to each other and to surrounding matter. This boundary in circles or globes is represented by their circumferences. In plain rectangular surfaces it is their linear extension or perimeter.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2638. J. Tate, an improvement or improvements in signalling on railways.
2670. W. Dowley, improved apparatus for enabling the passengers in a railway carriage to attract the attention of the guard and driver when required.
2675. A. Parkes, improvements in the manufacture of certain materials and combinations thereof, and the application of the same for waterproofing, insulating, and a variety of other purposes.
2681. L. P. G. Bellet and C. M. P. De Rouvre, certain improvements in the application of electricity as a motive power.
2687. J. H. Simpson, improvements in electric printing for telegraphic and other purposes, and in the apparatus to be used for such purposes.
2690. J. Solomon, improvements in lamps or apparatus for burning magnesium and other metallic substances.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2456. F. Tolhausen, improvements in apparatus for transmitting signals.—A communication.
2461. W. Anderson, improved apparatus for working railway signals.
2463. F. W. Shields, improvements in telegraphic posts.
2512. L. G. Loiseau, a new railway signal apparatus.
2518. M. J. Rice, improved pneumatic apparatus for communicating between passengers and guards in railway trains, as also between the guards, passengers, and engine driver of such trains.
2533. W. R. Sykes, improvements in apparatus for transmitting positive and negative currents of electricity.

PATENTS SEALED.

1126. W. T. Henley, improvements in telegraph wires and cables, and in apparatus used in their manufacture, parts of which improvements are applicable to other useful purposes.
1853. G. Lansdown, a method of providing a direct communication between any guard and any passenger in a railway train.

PATENTS WHICH HAVE BECOME VOID.

2574. T. Forster, improvements in reworking waste vulcanised india rubber.
2606. C. Cheyne and B. Moseley, improvements in the construction of apparatus for signalling on railways, by which improvements for signalling apparatus is rendered self registering or recording, and also applicable for measuring and recording the speed of passing trains and the time of their passage, part of which improvements is applicable for recording the speed of trains where signalling is no t required

TO CORRESPONDENTS.

C. EPPS.—Our opinion on the subject will be found in another part of the paper.
W. FROST.—The journal to which you refer was discontinued in June last.
H. K.—Favour us with further particulars, and we will see what can be done to remedy the evil complained of.
J. H. S.—1. The ratio of induction in an iron wire, as compared with copper, premising that the wires are of equal lengths and sectional area, and that they intersect equal magnetic fields, is as 1 : .162; copper being unity, of course this ratio will vary as the qualities of the copper and iron vary. 2. Yes.
E. W. SAMPSON.—Marine glue is made as follows:—Dissolve three parts of india-rubber in thirty-four parts coal-tar naphtha, aiding the solution with heat and agitation; add to it sixty-four parts of powdered shellac, which must be heated in the mixture till the whole is dissolved.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. SMITH & Co., Strand; J. ONWHYN, Catherine-street, Strand; Messrs. DAWSON & Co., Cannon-street, E.C.; Messrs. KENT & Co., Paternoster-row, London Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4s. 4d. | Half-yearly, 8s. 8d. | Yearly, 17s. 4d.

TO ADVERTISERS.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	1 7 6
Half ditto	2 10 0	Four lines and under (single col.)	0 3 0

Single Advertisements from the country must be accompanied with stamps in payment.

A FEW REMARKS ON INDIA-RUBBER.

UNTIL about the year 1819 little was known of the properties of caoutchouc. It was not used for any purpose, except for rubbing out pencil marks, before Mr. Thomas Hancock's attention was arrested by its peculiar properties. This gentleman, in the year above-named, commenced a series of costly, and for a long time fruitless, experiments to determine the best means of rendering rubber fit for the manufacture of articles of utility. Rubber has now become a staple commodity in the commercial market, it is employed extensively in the arts, and, from the circumstance of its being a good insulator of electricity, merits consideration in these pages.

Of the plants that yield caoutchouc the following, classified by Dr. Lindley, are the most prolific:—

I. *Siphonia elastica.*—This, which yields the caoutchouc of Para, is a tree inhabiting dense forests on the banks and tributaries of the river Amazon, where it is called the seringue. The chief district from which caoutchouc is obtained is, according to Wallace, the country between Para and the Xingui river. Another author, Aublet, speaks of the forests of French Guiana as abounding in this plant, where it is called siringa by the Garipon Indians, hevé by the natives of the Esmeraldas, and caoutchouc by the Chainas. According to this writer the trees are from fifty to sixty feet high, and from two to two and a-half feet in diameter. The bark is greyish, and by no means thick; the wood is light and white. The leaves each consist of three or more leaflets, attached by a joint to a long slender foot-stalk, and having an oblong form narrowing to the base; they are green above, but ash-coloured on the under side. The flowers are small, of a greenish hue, and hang in long loose bunches. The fruit is about the same size as a walnut with a rind that separates of itself, and a hard bony shell, splitting with elasticity into half-a-dozen pieces. In each cavity of the fruit are found from one to three seeds, about the size of a filbert-nut, but shining, and mottled with brown upon grey in the manner of the castor-oil seeds. This fruit is agreeable to the taste, and is consumed largely by the Indians, who experience no great inconvenience from eating them, notwithstanding their relation to the West Indian purging nut. Aublet himself was able to eat them without experiencing any unpleasant effects. It was long supposed that there was only one species of siphonia; but the enterprise of Mr. Spruce, a distinguished naturalist, has made botanists acquainted with several others, among which may be included the *siphonia lutea*, found near Panuré, on the river Uaupes; *siphonia discolor*, from the north bank of the Amazon, at its junction with the Rio Negro, and also from Panuré; *siphonia paucifolia* and *siphonia rigidifolia*, from Panuré; and *siphonia spruceana*, from the province of Para.

II. *Hancornia speciosa.*—Under the title of mangaba, or mangava, the Brazilians obtain a fruit the produce of an apocynaceous plant, to which botanists have given this appellation. It is very common in the vicinity of Pernambuco and Olinda, and is also found at Bahia. Gardner describes it as "reaching to the size of an ordinary apple-tree, though its small leaves and drooping branches give it more the appearance of the weeping birch. The fruit is yellow, slightly streaked with red on one side, about the size of a plum, and of delicious flavour. When in season it is brought to Pernambuco for sale." According to M. Claussen, the tree is found on the high plateaux of South America, "between 10° and 12° south latitude, at a height of from 3,000 to 5,000 feet above the level of the sea." The leaves grow opposite each other on the slender branches, about two inches long, oblong, suddenly ending in a blunt point, having a glossy surface, with fine parallel veins. The flowers are slender, tubular, and about one inch and a-half long, growing singly, from among the leaves.

III. *Ficus elastica.*—This plant, indigenous to India, yet so familiar to home horticulturists, is described by Roxburgh. It is known in its native wilds—*i. e.*, the Pundia and Juntipoor mountains, which bound the province of Silhet on the north—by the name of kasmeer, and grows fully as large as the sycamore of this country. The trunk is said to be from five to six feet in circumference, the wood soft, porous, of a light brown colour, and unfit for the uses to which ordinary timber is applied. Its branches are numerous, spreading and rising in every direction, forming a very extensive and shady head. The figs grow in pairs from the base; when ripe they are oval, about the size of an olive, smooth, and of a greenish-yellow colour. Our author says that with the milk, while in its recent state, "the natives of the mountains, a barbarous race, coat the inside of the rude utensils that are intended to hold fluids," and that caoutchouc itself, being inflammable, "furnishes them with candles and flambeaux."

IV. *Urceola elastica.*—Mr. Howison, a surgeon of Prince of Wales' Island, relates that while clearing a way through a jungle with cutlasses it was remarked that a vine had been divided, the juice of which drying on the blade of the weapon possessed the properties of American caoutchouc. The vine was about as thick as a man's arm, with a strong, cracked, ash-coloured bark. It had joints at a small distance from each other; often sent out roots, seldom branches; ran along the ground to a great length, and at last rose upon the highest trees into the open air. It was afterwards met with on the west coast of Sumatra, and other Malay countries. Roxburgh describes its leaves as being opposite on short stalks, oblong, pointed, a little rough, with a few scattered hairs on the underneath. The flowers are small, of a dull greenish colour, and are produced at the ends of the shoots and bunches like those of a lilac bush. The seed vessel is laterally compressed into the form of a turnip, is wrinkled, leathery, and about three inches in diameter.

The best description of rubber is obtained from Para. Stimulated to spasmodic exertions by profits which equal in a very few days the wages of a month given to ordinary work, the half-civilized population of the province, neglecting the culture of the soil, and those industrial pursuits by which they might be permanently benefited, flock to the marshy districts, where the rubber tree is found. There, passing many months of the year with slight shelter, and slighter clothing—regardless of sanitary regulations, and observing no precautions against malaria, which pervades the banks of the Amazon and its tributaries—ravaged by intermittent fevers, and spending in nightly orgies the money so easily acquired, their numbers are fearfully diminished and the population demoralized, with no benefit to themselves and no permanent advantage to the State, which is poorly compensated by a heavy export duty for the sacrifice of its prospective prosperity. As the rubber tree is found upon the public domain, upon which to labour without

restriction is free to all, it is not likely that these pernicious influences will be speedily counteracted. The sole difficulty in procuring rubber is to gain access to the tree. In order to effect this object it becomes necessary to cut paths through the virgin forests. When this is accomplished the Indians make an incision in the tree, about six feet from the ground, and catch the milk, as it flows from the puncture, in rude bowls of clay, which hold about half-a-pint; these vessels are filled in about three hours, if the tree be tolerably fruitful. When the first cutting ceases to yield they make another incision lower down the tree, and so on until four cuttings are made, and the tree is exhausted. After a tree has been once subjected to this process it requires a period of two years to elapse before it is in a condition to yield a further supply. When the process of extraction is concluded the milk is accumulated in larger vessels, subjected to heat, and rendered in a fit state for market.

Previous to 1840 rubber was exported in but small quantities, and chiefly in the form of shoes. After that period, new applications of the material having been discovered in England and the United States, the export of shoes was discontinued, but shipments in bulk largely increased, which increase, owing to circumstances affecting consuming markets, has since been progressive. In the last ten years there has been exported from Para 1,059,952 arrobas of fine rubber, and 378,792 lbs. of ordinary. The Brazilian arroba is rather more than 32 lbs., and hence the total shipments have been upwards of 20,600 tons. Formerly the principal shipments were to the United States, now the largest exports are to the United Kingdom. Last year 65,649 cwts. were received in Great Britain from all quarters. From the Port of Guayaquil, on the coast of the Sea of Ecuador, 2,227 cwts. were shipped in 1863.

"Caoutchouc," says Professor Brande, "is sometimes called *gum elastic*, but it has none of the characters of a gum, being perfectly insoluble in water; nor is it a resin, for it is insoluble in alcohol; but ether, which has been washed so as to deprive it of alcohol, dissolves it, with the exception of impurities, and leaves it on evaporation in its perfectly elastic state; it also dissolves in chloroform, and in sulphuret of carbon, and in some of the essential oils; but its most common and useful solvents are rectified naphtha and oil of turpentine."

The uses of rubber are as various as the requirements of the public; it is susceptible of manipulation for a thousand purposes; but what concerns us most, in a proper application, it is by far the best material for the manufacture of submarine telegraph cables. Mr. Latimer Clark, in his evidence before the Submarine Telegraph Committee, when asked his opinion of caoutchouc as an insulator, replied, "It stands very high indeed as an insulator, and its specific inductive capacity is very low"—two of the most important requirements in telegraphy—"therefore, as a material it is peculiarly well adapted for use in submarine cables, and it has the great advantage that high temperature does not injure it. I have seen many pieces of it in a state of decomposition from causes which at present I do not understand. By some it is attributed to the action of the copper, by some to the use of greasy wire in the manufacture, and by others to the use of an inferior rubber. I have had specimens which were laid down by my brother, Mr. Edwin Clark, in 1850, in several tunnels on the Lancashire and Yorkshire and North-Western Railways. I have also examined specimens which were laid in the Box tunnel long prior to that time. All those specimens have cotton round the copper wire before the india-rubber is placed in it, and I find that no particular decay has taken place in these wires, and they give me the impression that india-rubber will eventually prove to be a highly permanent material." Similar testimony is borne by Mr. John Fuller, in his evidence. He says: "The insulating property of india-rubber is admitted on all hands, and its less induction is a well-known fact. These are facts which I saw at once on entering on the manufacture. It was not generally known, and no one would receive it as correct; many gentlemen that I spoke to about the less induction of india-rubber had no idea of such a thing, and they could not think it possible. There was a notion existing among electricians a year ago that the greater the insulation, the greater would be the induction." Mr. Varley recommends the application of india-rubber in its native state, and asserts that, if wires were treated with caoutchouc in this condition, "an insulator would be obtained far superior to gutta-percha, very tough, sound, and not liable to decomposition." * * * * "Added to which, the inductive capacity of india-rubber is much lower than that of gutta-percha, and consequently the speed of transmission through an india-rubber covered wire would be much higher than that through a gutta-percha covered wire." Notwithstanding these emphatic declarations of the superiority of india-rubber as an insulator over gutta-percha, the latter material is now the more generally employed in the manufacture of submarine cables. There are undoubtedly several conditions to be fulfilled in the coating of wire with india-rubber, but these are now perfectly well understood, and several patents are extant for improvements in the application of caoutchouc, which remove hitherto believed-in defects to a reminiscence. Messrs. Wells & Hall affirm that in no instance in which their patent has been conformed to have their wires shown the slightest indication of decay. Mr. Hooper advocates the use of vulcanized rubber—*i.e.*, caoutchouc treated with sulphur—(which resists the influence of water in a remarkable degree), and alleges that this is the most effective insulating material ever produced. Messrs. Macintosh guarantee perfect insulation in long lengths of deep-sea cable, and perfect protection from oxidation and the ravages of marine insects. One great objection to the employment of india-rubber for submarine cables was the difficulty of making joints in the material. All occasion for uneasiness on this account is now removed, for Mr. Hooper's recent experiments prove conclusively that joints can be made so perfect as to defy detection. "Caoutchouc, like gutta-percha," says Dr. Miller, "is liable to deterioration by exposure to the action of oxygen in the presence of solar light." This fact is readily admitted, but the means now available for the protection of cable cores from the action of oxygen, both in air and in water, lead us to hope that the day is not far distant when this valuable vegetable product will supersede its more costly and less efficient rival. On its intrinsic merits rubber should have been employed in telegraphy far more extensively than it has hitherto been. Vested interests have long stood in the way of its application, but the facilities which have been offered patentees, for bringing the claims of their inventions before the public, by the Joint-Stock and Limited Liability Companies' Acts, will tend in no small degree to break down the monopoly which has existed too long for the good of telegraphy.

THE WONDERS OF THE WORLD.—The greatest cataract in the world is the Falls of Niagara, where the water from the great Upper Lakes forms a river of three quarters of a mile in width, and then, being suddenly contracted, plunges over the rocks in two columns to the depth of 170 feet each. The greatest cave in the world is the Mammoth Cave in Kentucky, where any one can make a voyage on the waters of a subterranean river, and catch fish without eyes. The greatest river in the world is the Mississippi, 4,100 miles in length. The largest valley in the world is the Valley of the Mississippi. It contains 500,000 square miles, and is one of the most fertile and profitable regions of the globe. The largest lake in the world is Lake Superior, which is truly an inland sea, being 430 miles long. The greatest natural bridge in the world is the Natural Bridge over Cedar Creek in Virginia. It extends across a chasm 80 feet in width and 250 feet in depth, at the bottom of which the creek flows. The greatest mass of solid iron in the world is the Iron Mountain of Missouri. It is 350 feet high and two miles in circuit. The largest number of whale-ships in the world are sent out by Nantucket and New Bedford. The greatest grain port in the world is Chicago. The largest aqueduct in the world is the Croton Aqueduct in New York. Its length is 40½ miles, and it cost twelve and a half million of dollars. The largest deposits of anthracite coal in the world are in Pensylvania—the mines of which supply the market with millions of tons annually, and appear to be inexhaustible.—*American Artisan.*

ELECTRIC TELEGRAPHS IN THE UNITED KINGDOM.

The Government returns are, perhaps, the most reliable data on which conclusions as to the progress of the telegraphic system can be based; and although these are not very comprehensive in character, they afford at least information which it would be difficult to procure from private sources. In a recent issue of this journal we stated that a more extensive business might be transacted on telegraph lines without any perceptible increase in the working expenses. This statement is strikingly corroborated by an official document presented to both Houses of Parliament, from which it will be seen that in several instances the mileage has not been materially augmented, while the traffic has increased from 10 to 20 per cent. on the previous year's operations.

From a volume of Miscellaneous Statistics, recently published, we extract the following tabular statement of electric telegraphs open to the public in the United Kingdom in each of the years 1861, 1862, and 1863:—

Telegraph Companies.	Length in Miles of Telegraph Lines.			Length in Miles of Wires used.			Number of Stations open for the Public.		
	1861.	1862.	1863.	1861.	1862.	1863.	1861.	1862.	1863.
Electric and International	6,727	7,597	8,230	32,787	35,066	39,042	772	909	1,022

The United Kingdom	65	88	172	11,549	133,514	226,729
Total	5,132	5,522	6,196	2,123,589	2,676,352	——
Submarine	54 exclusively for Continental traffic.	23 exclusively for Continental traffic.	51 exclusively for Continental traffic.	About 230,000 to and from Foreign Countries.	310,595 to and from Foreign Countries.	345,784 to and from Foreign Countries.

* The number of messages to and from the Continent transmitted jointly by this company and the Submarine Telegraph Company, and the number of messages for railway companies, newspapers, and news-rooms, are not included with the messages for the public, but are estimated at about 250,000 messages per annum.

† The South-Eastern Railway Company has no working arrangements with either of the electric telegraph companies.

‡ Exclusive of private telegraphs provided by this company for firms and persons having two places of business, and the London Fire Brigade system of telegraphs.

§ This additional mileage and stations was only completed and opened in November, 1863.

THE RUSSIAN-AMERICAN TELEGRAPH.

ALTHOUGH our readers may be well posted in this project, an account of its inception, the leaders in the enterprise, the route to be followed, and the date on which it is expected that Russia and America will be joined together by the telegraph—all these particulars from the pen of the Cleveland correspondent of the *New York Herald*—will doubtless prove interesting:—

"The subject of a telegraph between the continents has been agitated ever since the magnetic telegraph was known to be a success. Various routes have been proposed, and on one the experiment has been tried, and is about to be repeated. That a cable can be successfully laid between Newfoundland and Ireland has been demonstrated to the world; the matter of its permanent success remains to be tested. This will be tried by the new cable, to be laid down under the direction of Mr. Field. The experience of telegraph men is not generally in favour of submarine lines, though there are several that have been working well through a series of years.

"The managers of the Western Union Telegraph Company have been for a considerable time looking at the project of a telegraph to Europe through Asiatic Russia. The company now have their lines extending from Buffalo and Pittsburg as far west as Salt Lake City, where they connect with a California line to San Francisco and Oregon. They touch all the principal cities of the West, and form a very important link in the girdle that Puck would put about the earth in forty minutes. Such uniform success has attended their enterprise that they are constantly desirous of extending their power, and from the first moment of conceiving the design of an intercontinental telegraph they have never allowed tho subject to rest.

"The new company is organised with a capital of ten millions, and is to be distinct from the Western Union, though controlled by the managers of the latter concern. J. H. Wade, of Cleveland, is President of the Company; Colonel Anson Stager, George B. Hicks, Hiram Sibley, and others whose names are not now at hand, are directors and leaders in the enterprise. The offices of the company are in this city in the Western Union building. A large number of telegraph men throughout the country are interested in the success of the work. Mr. Perry McD. Collins has been the labourer broad with the Emperor of Russia to secure the privileges which the company have obtained.

"The friendly feeling expressed by Russia towards the United States has aided much in the preliminary work. As soon as the subject was proposed to the Emperor he expressed his hearty concurrence in the plan. After some time he proposed to build a line half way from St. Petersburg to Washington, on condition that the United States would build the other half. Nearly every enterprise in Russia, whether of railway or telegraph, is carried out by the Government, and not by private effort. At first the Emperor hesitated to grant privileges to a private company, but after a time he consented to do so. The American company has obtained a perpetual charter, which is exclusive for three years, for the building and working of a line through the Russian possessions to the mouth of the Amoor river. This point is about half way between St. Petersburg and Washington. The Russian portion is finished from St. Petersburg to Irkoutsk, and from the mouth of the Amoor three hundred miles west, leaving but about nine hundred miles unfinished. This will be completed during the present season, and is all paid for by the Russian Government.

"Mr. Wade, the President of the American company, thinks the line will be working from Washington to St. Petersburg in two years from the present time. A year will be consumed in fixing upon a route and in distributing material, and when this is accomplished the greatest difficulties of the enterprise are overcome. The route to the Pacific coast is not yet fixed. One route proposed is from Fort Laramie, or Salt Lake City, through the Idaho gold mines to Portland, Oregon. Another is by way of St. Paul, Minn., through Fort Garry and the Selkirk settlement of British North America to Victoria and Vancouver's Island. Thence it is probable the line will follow the coast by the fur posts of the Russian Fur Company to Behring's Straits, and thence down the Asiatic coast to the mouth of the Amoor. In case any unforeseen difficulties present themselves in Behring's Straits, it is proposed to lay a cable from Cape Romanzoff to Isle St. Lawrence, and thence to the Asiatic coast at Cape Tchuktchi. A glance at a large map of the world will show that this route is shorter than the one by Behring's Straits, though it requires a cable of greater length.

"The chain of the Aleutian Islands was first proposed, but is not at all likely to be adopted. It would require an immense number of submerged wires, and be in danger of being frequently out of order. The Western Union Company's experience with its cables at crossings of rivers is not such as to induce belief in their general feasibility. So little is the reliance upon their success, that they propose to keep a steamer constantly at Behring's Straits, with cables on board ready for laying whenever the line shall give out. The smallest accident may disable a submerged wire, and when once broken there is no means of repairing. The Aleutian Islands chain requires such a series of cables that a single steamer would not be sufficient for the purpose.

"In addition to their charter as a telegraph company, the new concern has received the right to trade anywhere in Russian territory. Hitherto trade has been exclusive with the Russian Fur Company. This company, like the Hudson Bay Company, has lost the charter for exclusiveness; but the trade has so far diminished in the past few years that it is not now worth the formation of rival companies for purposes of trade alone. The telegraph company could be a formidable rival in the matter of trade, as it would carry on the business in connection with its direct enterprise. The Russian company has proposed that an arrangement be made that shall be mutually advantageous. This will probably be done, and the telegraph and fur companies work in harmony. The former will make use of the ships, posts and men of the latter to build and keep the line in order, and will make no interference in trade matters.

"A ship is about to sail from New York with material for the line. Captain Bulkley, who has charge of the Company's interest on the West Coast, has already left for San Francisco, and will be ready to distribute the material as soon as the ship arrives. Mr. Collins has gone to Europe to further the company's interests in that quarter, in England and Russia. Nothing now stands in the way except the completion of the line.

"To give an instance of the rapidity of telegraph building, when set about in earnest, I will state a fact of history in connection with the Pacific line now in operation. Early in 1861 Mr. Wade went to California to arrange about their connections. He contracted with a California company to meet them at Salt Lake. In order to stimulate all parties to exertion, it was stipulated that the one first opening its line to Salt Lake City should receive fifty dollars a day forfeit from the other, as well as the earnings of both ends of the line, until the two routes joined. The Western Union Company had not expected to build the line that year; but, under the stimulus of Mr. Wade's contract, they set to work and pushed through in about four months. The cost of construction was actually less than if they had taken plenty of time for the work.

"The line from Omaha to Salt Lake runs through the Indian country, and a part of the way is off the main travelled route. There are less derangements than between Buffalo and St. Louis, and the managers say that it works more hours in a year than their other lines. They assert that they prefer an uninhabited to a well settled country, as far as working the route is concerned. One feat has been performed on this line never performed in civilisation. On several occasions the operator at Chicago has worked through to Salt Lake, sixteen hundred miles, without repetition. The wonderfully dry atmosphere on the Plains is highly favourable to telegraphing.

"During the late Indian troubles the red men never interfered with the wires. This is due to a ruse practised on them by Mr. Creighton, Superintendent between Fort Hearny and Salt Lake City. Mr. Creighton caused them to believe that the telegraph was the breath of the Great Spirit. Thus believing, they carefully abstained from interfering."

EFFECT OF LIGHT ON THE MAGNETIC NEEDLE.—Few persons are aware that light exerts a perceptible effect on the action of the magnetic needle. The Swedish philosopher, Wrede, totally excluded light from his magnetic observatory, with the exception of a subdued light, at a considerable elevation, vertical to the horizontal needle, while the arc was read off by a telescope, at a distance of several yards from the instrument. Means with the same end in view ought to be adopted in every magnetic observatory, otherwise no reliance can be placed on the observations. It is evident that the more deliberately the magnetic needle is suspended, the more obnoxious it will be to the effect of artificial light in the operation of reading off the instrument. In proof of the effect of every description of light on the magnet, Sir John Ross mentioned that during his last voyage in the Felix, when frozen in about 100 miles north of the magnetic pole, he concentrated the rays of the full moon on the magnetic needle, when he found that it was five degrees attracted by it.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XV.

A.D. 1840, January 21.—No. 8345.—Wheatstone, Charles, and Cooke, William Fothergill.—"Improvements in giving signals and sounding alarms at distant places by means of electric currents," consisting of:—

A signal apparatus, by which the letters of the alphabet are presented at an opening in a dial plate, by means of an electro-magnet in the circuit, which acts upon the pallets of an escapement similar to an "echappement à cheville," put in motion by independent clockwork. When the electric current passes, the electro-magnet attracts a keeper attached to the end of a "sliding spindle" carrying the pallets, which action takes away the detaining pallet, releases a tooth of the escape-wheel on the dial axis, and brings the other pallet into action, so that the wheel is advanced only half a tooth. On the electric current ceasing, a spring restores the sliding spindle to its original position, and enables the escape-wheel to advance another half tooth; and so on until the required signal appears at the dial plate opening, when a pause is made, and the same process gone through for the other signals. The escape-wheel may be driven without clockwork, by means of spring pallets (attached to a sliding spindle parallel to its axis) in connection with the electro-magnet and reacting spring. A magnetic needle and coil may also be used (by reversing the electric current) in connection with pallets and an escape-wheel, to give motion to the dial.

A "communicator," having a dial plate similar to that of the signal apparatus, and radial arms to work it, one to each signal. Under the dial is a metallic circle inlaid with wood, the metal of which is connected with one circuit wire, the other circuit wire from the battery being only brought into metallic contact with it when a spring is in contact with the metallic portion of the circle. The rotation of the dial plate by the operator makes and breaks the circuit alternately, so that when this instrument is used in connection with the signal apparatus, it moves the disc according to the signals required to be given. When the communication is finished, the dial plate is made to indicate blank, and the main circuit is completed by means of a single inlaid piece of metal in a wooden circle, against which a spring presses, thus enabling signals to be received; at the same time connection with the battery is broken.

An electric alarum. In the signal apparatus, the electro-magnet is mounted upon a "slider," so as to be moved, by a suitable "stem," opposite to another piece of soft iron fixed to a sliding spindle (carrying a detent) that releases the fly-wheel of the alarum clockwork whenever the electric current passes round the magnet in that position. This train has a "serrated wheel," which "by acting on suitable pallets, moves the hammer of the alarum backwards and forwards so as to strike the bell."

An alarum apparatus, in which a hammer is made to strike upon a stop at certain regular intervals by clockwork always in motion; when a magnetic needle is deflected by the completion of the circuit, it places itself against a detent, so that the hammer strikes upon it, releases the clockwork, and enables the alarum to sound. An electro-magnet and keeper may be used, instead of the coil and needle, to enable the hammer to act on the detent.

A magneto-electric machine, that may be used in connection with the signal apparatus above described. The current is made to circulate in one direction by means of an inlaid wooden disc on the axis of the armature, in connection with springs in metallic contact with the main wires; the disc is inlaid with two insulated metallic semicircles respectively in connection with each terminal of the armature coil; thus the to-and-fro current generated by the machine is reversed. The machine is driven by a cog-wheel and pinion, the cog-wheel having twelve pins, so disposed that, by the motion of the wheel through a space equal to the distance between them, the armature moves through half a revolution. Twelve signals are thus made without the "communicator," and are all that this machine can make with the above described signal apparatus, as its electric current is only of momentary duration, and the electro-magnet cannot act a sufficient time to convey a signal by stopping the pointer.

A signal apparatus, in which the force of two electro-magnets in the circuit is made to act, through pallets and an escape-wheel, on a hand or moveable dial without the reaction of a spring. The pallets have a tail-piece (free to vibrate between the poles of the two electro-magnets) which is attracted to one of the electro-magnets when the instrument is at rest, in consequence of the circuit including the electro-magnets being then closed; by this means the clockwork is prevented from running down. Three main wires are used with this instrument; one which connects dissimilar poles of the batteries; a second connecting similar terminals of the "right-handmost" magnetic coils; and a third connecting similar terminals of the "left-handmost" magnetic coils. When the circuit is completed through the two main signal wires, so that each conveys half the electric current, both the magnets are excited and the signal apparatus can receive signals. The "communicator" is placed concentric with the dial, and the current is conveyed to the magnets alternately, or both at once, by means of a pinion whose axis carries a metal wheel inlaid with wood with which the remaining battery wire is connected, and against which springs, connected with the remaining coil terminals, press; the pinion is moved by a toothed wheel on the dial axis. In order to enable intermediate stations to work this signal apparatus with the batteries at the terminal stations, the intermediate apparatus have two inlaid metal wheels, one for each magnet; this instrument is portable. The dial or hand may be worked by the electro-magnets only, a detent to ring an alarum (when a stop is pulled out) may be released by the completion of the circuit without shifting the magnets, and the keepers of the magnets may be attached to the pallets themselves. In all the above signal apparatus, either a dial revolving behind a perforated dial-plate, or a hand revolving over a fixed dial-plate, may be used. Letters Patent, Nos. 7390 and 7614 are referred to.

A.D. 1840, March 3.—No. 8407.—Shore, Joseph.—"Improvements in preserving and covering certain metals and alloys of metals." This invention "relates to a mode of obtaining or applying a permanent covering of copper or of nickel by means of galvanic batteries on articles manufactured of wrought or cast iron, tin, lead, and copper, and of alloys of such metals, such covering acting as a preservative to some of those metals and alloys of metals, and in other cases as a superior surface." For this purpose "an open vessel" "of wood or of earthenware," divided "into two compartments by a partition of unglazed earthenware or other porous substance," is taken. Into one of the compartments "pure water slightly acidulated, by preference, with sulphuric acid," is placed; and into the other a solution of "sulphate of copper or nitrate of nickel, whichever is to be used, as the "covering metal." These metallic solutions must be "kept up to a neutral strength." A piece of zinc is placed in the first-mentioned compartment, and connected by a copper wire to the article to be covered, which is placed in the metallic solution. The articles are, preferably, cleansed by submitting them to a low red heat when covered with sand, charcoal, or black lead, in a crucible, and "permitting the same to cool" before covering them. The solutions may be either used hot or cold, and "the longer the articles are under operation the thicker the covering." Large articles are covered separately, "small articles, such as iron rails" [nails?], are placed in a wire "basket" connected by a wire to the zinc plate. The article should be "moved, from time to time, to prevent any part or parts being left uncovered."

A.D. 1840, March 25.—No. 8447.—Elkington, George Richards, and Elkington, Henry.—"Improvements in coating, covering, or plating certain metals," consisting of:—1st. "Coating," &c., "copper and brass with silver," by immersing the article, cleaned and silvered (See Letters Patent, No. 7496, or the second improvement hereinafter mentioned) in a solution of nitrate of silver; expelling the acid by heat; and fusing on the coating by immersion in fused borax; the cooled article is then boiled "in dilute sulphuric acid" "until the adhering borax is all dissolved." "For a finish," the article is preferably electro-coated with silver, as hereinafter described. 2nd. "Coating," &c., "metals with silver." The cleaned articles are, by preference, immersed in a solution of oxide of silver in "prussiate of potash (cyanide of potassium)" by boiling. For a thicker coat a galvanic current is used, by means of a single cell apparatus. Oxide of silver must be added "from time to time." "Prussiate of soda or other analagous salt," or "pure ammonia," may be used either with or without a galvanic current, or a "neutral salt" of silver in connection with a galvanic current, the article having previously received a thin coating by the "cyanide of silver" solution. 3rd. "Coating," &c., "metals with gold." The cleaned articles are, preferably, immersed in a solution of comminuted gold, or oxide of gold, in "prussiate of potash" by boiling. For a thicker coat, a galvanic current is used as described for silver. The solution must be kept "saturated with gold." Double

and "haloid salts" of gold, and oxide of gold, or metallic gold dissolved in "any soluble prussiate, or "any other analagous salt," may be used, either with or without a galvanic current, as for coating with silver. In these two last-mentioned improvements the article may either be of metal or coated with metal. 4th. Iron is prepared "for receiving a coating of copper," &c., by immersing it, connected with a strip of zinc, in dilute sulphuric acid, thus causing it to be "electro-negative" whilst cleaning. It is then placed in a "brass vessel" containing an acid solution of sulphate of copper, and having thus received "a thin film," is ready to be covered with any metal by a galvanic arrangement similar to that described for silvering, or "by other known means."

A.D. 1840, May 7.—No. 8499.—Grover, Henry Montague.—"An improved method of retarding and stopping railway trains." This invention consists "in the application of the powers of an electro-magnet, or of electro-magnets, or of magnetism generally, whether applied directly or indirectly to any wheel or wheels upon which a train or any portion of a train of carriages, or other vehicles upon any railway, moves, or in any other manner." The specifications and drawings describe and show an electro-magnet "applied to the face of the tire of one wheel of a railway carriage, called a truck." An electro-magnet is fitted into a wooden block or box, covered with a lid, and is suspended from a transverse rod at the bottom of the truck, so as to hang within "half an inch, more or less, according to the power of the magnet from the tire of the wheel." On the connection of the wires from the battery, which is placed in the truck, the adhesion of the electro-magnet to the tyre of the wheel "will impede or totally prevent its turning round, and thus retard or stop the train of which the carriage, the wheel of which is thus acted upon, forms a part. Any number of the wheels of a carriage or train may, of course, have these magnets applied to them, and the retarding of each such wheel will be in proportion to the power of the magnetism so elicited and applied."

A.D. 1840, August 27.—No. 8610.—Lockett, Joseph —"Certain improvements in manufacturing, preparing, and engraving cylinders, rollers, or other surfaces for printing or embossing calicoes or other fabrics," relating to:—1st. The application of galvanic electricity to "recoating, covering, or thickening" the cylinders, &c., used for calico printing; or to make new cylinders. This is done by taking a "mould or shaft," which may either be a conductor of electricity and "retained as a portion of the cylinder," or a non-conductor "subsequently rendered a conductor" by any of the usual means, and then removed from the cylinder when it has attained the requisite thickness." The "mould" is then covered with copper by the ordinary process of electro-deposition. 2nd. A "method of preparing surfaces by galvanic or voltaic electricity, applicable to cylinders, plates, or blocks for printing or embossing calicoes and other fabrics." When any of the engraved ground is required to be obliterated or "rendered plain," those portions are left exposed, whereas the rest of the surface is coated with varnish; the exposed part is then coated with copper by galvanic agency in the usual manner. 3rd. A "mechanical contrivance" for "cleaning, filing, or turning off the superfluous portions of the copper thus deposited upon rollers or cylinders." This consists of a "rotary cutting or filing tool" applied "either to the ordinary slide lathe or the engraving machine commonly used for cylindrical engraving" and acting upon the cylinder, the cylinder being properly "supported by and revolving on the mandril" of the lathe. The "filing tool" is carried "from end to end of the roller" by a screw extending the whole length of the lathe, "or it may be slidden to any part of the bed by hand or otherwise," and has proper adjustments for regulating its speed and depth of cut.

A.D. 1840, September 10.—No. 8625.—Dent, Edward John.—"Certain improvements in clocks and other timekeepers," consisting:—1st. "In giving the impulse to the pendulum of a clock at the centre of percussion, or as near as practicable to that centre." 2nd. "In producing a compensation for the expansion and contraction of the length of the pendulum arising from changes of temperature, by causing the arcs of oscillation to vary in an inverse ratio to the variations of the length of the pendlum" [pendulum?]. 3rd. "In combining three or more main springs and barrels to act simultaneously, without the medium fuzee, upon the train of wheels of a chronomer" [chronometer?] "or other timekeeper." 4th. "In connecting three or more main spring arbors with a common arbor, whereby all the springs may be wound up at the same time by one application of the key." 5th. "In withdrawing, as much as practicable, the atmospheric air from the interior of an air-tight case containing a chronometer, and in filling the space with a dry non-corroding gas, such as hydrogen." 6th. "In *the application of the well-known voltaic or electro-metallurgic process* to the depositing of a thin film of gold or other metal, incorrodible by the atmosphere, upon the steel balance spring and the compensation balance, the surface of which having been cleaned with alkali or acid immediately previous to the application, in order that the metallic adhesion may be perfect and rust prevented, and consequently one cause of variation in the rate of chronometers is thus avoided."

A.D. 1840, September 24.—No. 8644.—Pinkus, Henry.—"Improvements in the methods of applying motive power to the impelling of machinery, applicable, amongst other things, to impelling carriages on railways, on common roads or ways, and through fields, and vessels afloat, and in the methods of constructing the roads or ways on which carriages may be impelled or propelled," relating to:—1st. "Propulsion on railways" by means of the "gaso-pneumatic" force. 2nd. "Propulsion on canals" by means of the "gaso-pneumatic" force. 3rd. "Applying the aforesaid gaso-pneumatic principle to impelling machinery, to wit, the impelling engine described in my said former specification, dated twenty-fifth day of February, 1841," [Does not this refer to No. 8207, which was enrolled February 25, 1840?] and to "the purpose or purposes of a fire-engine." 4th. "Effecting propulsion" on railways or canals by "steam power, in combination with the same, or parts of the same impelling machinery or apparatus, in lieu of gaso-pneumatic power." 5th. Effecting propulsion on railways, common ways, and canals, and through fields, by the application of electrical force, however generated. This invention is applied to agricultural purposes, by either erecting a central station in which "an electric battery or batteries" are placed, or constructing "wells or tanks," too deep in the ground to interfere with agricultural operations, from which pipes containing bundles of insulated wires are laid, having at convenient places "vertical branches" with "boxes," in which are the loose ends of the wires; the wires are coloured to distinguish their electric polarity. "To put implements into action, a locomotive engine is constructed, with a drum carrying and winding up the battery wires, and a "Taylor's" (See Letters Patent, No. 8255?) or any other electro-magnetic engine. Trains are stopped by electric agency as follows:—Batteries are placed at convenient distances along the line, and between each line of rails a light hollow "railway bar" is laid (in half mile lengths), having continuous bars of wood carrying two copper strips insulated from one another; the copper strips are in connection with two insulated wires in the interior of the hollow rail, thence with one of the batteries. By means of "an electro-magnetic coupler" "composed of two masses of copper," insulated from one another, and suspended by a moveable joint to the locomotive engine, the stationary battery is connected at will with a "Taylor's" (or any other) electro-magnetic engine on the locomotive, which enables any person having charge of the railway to shut off the steam and blow the whistle. The "Taylor's" engine acts on the shut-off valve and steam whistle by means of a pulley, cord, and lever. A similar apparatus may be placed in the break carriage, and actuate the break when required. An electro-magnetic break is described, in which "a flexible armature" of "thin laminated plates lying one on another," is attracted to an electro-magnet, and actuates suitable levers. To prevent collision, a battery on the locomotive may complete the circuit, whenever it gets on the same half mile length as another train, through the strips on the wooden bars. "Taylor's rotary wheel," or any other electro-magnetic engine, may be used as "the moving power on a locomotive engine," "by taking up the electric force from the wires" laid down between the rails. An electro-magnetic beam engine is described and shown, consisting of electro-magnets with horizontal surfaces, on each side of the beam, acting alternately on a "flexible armature," "formed of thin laminated plates lying on one another," with one edge of which they are connected, thus enabling the beam to vibrate, and rotate a fly-wheel. This engine has a circuit breaker, consisting of a weighted lever in contact with one or other of two plates, according as a hammer jointed to an excentric stud on a rotating "circular cam" rests upon the lever plate or not. The electro-magnetic force may be used on canals by means of the "dynamic impeller;" this consists of a frame travelling on a "suspension rail" (one of which is laid on one or both margins of the canal). To keep it properly balanced on the suspension rail, the dynamic impeller has, besides "travelling wheels," "adhesion wheels" bearing against the sides of the rail, on whose axis pullies are attached, that carry a "cord or tow rope" passing round a pulley in the vessel; there are also weights to keep the principal weight below the centre of gravity. The wooden bars

carrying the battery wires are supported on each side of the rail, and an electro-magnetic engine may be placed either on the "impeller" or in the vessel. The electro-magnetic force may be applied to railways by means of a "differential railway." Fixed engines, erected at suitable distances apart, give motion to bands passing round horizontal wheels mounted between the rails, the bands thus traversing beneath the carriages. The motion is communicated to the carriages by pullies or "impelling wheels," in a trench, at certain distances apart, which work into a flange bar at the bottom of the carriages. The electro-magnetic force may also be applied to putting "impelling engines" in motion, in manufactories, by establishing "electric metallic circuits" from fixed stations containing batteries. "The combinations of method and apparatus" set forth in this specification for applying electric currents may be used "for the purposes of lighting places." "The valve main of the gaso-pneumatic railway" may be unsealed by a heated electric wire.

A.D. 1840, October 1.—No. 8650.—Talbot, William Henry Fox.—"Improvements in producing or obtaining motive power" by means of galvanic electricity. In one engine, the galvanic current is made alternately to generate the mixed gases from the decomposition of water under a piston, and to explode those gases, thus giving motion to a fly-wheel shaft. In a second engine, a lever is moved downwards, and then up again, by means of an electro-magnet, and the reactive force of a rod free to move after the armature has reached the magnet. The temporary magnetism attracts the lever (it being fixed to the armature) till the armature comes into contact with the magnet; the electric current then ceases, but a rod (passing through a hole at the end of the lever) attached to a crank, continues moving, and on its upward motion raises the lever, which is then ready to be again attracted by the magnet. A variation of this plan is described and shown, in which the armature merely rests in the lever, and several magnets and armatures may be used; in this case the lever itself continues its motion after the armature is in contact with the magnet. Other plans may be used, in which only the armature itself is stopped, the rest of the machinery continuing its motion. In a third engine, motive power is obtained by the alternate expansion and contraction of a gas, vapour, or fluid, heat being applied and withdrawn at proper intervals by a galvanic battery. A strong iron U-shaped tube, partially filled with mercury, has one leg in connection with a piston, the other leg closed at the end and filled with solid carbonic acid; this soon liquifies, a part becomes gaseous, and motion of the piston is produced by passing a galvanic current, at proper intervals, through a thin piece of metal (thus heating it) in the carbonic acid.

A.D. 1840, October 7.—No. 8656.—Spencer, Thomas, and Wilson, John.—"Engraving metallic surfaces" by means of "voltaic electricity." The surface to be engraved is coated with varnish or "etching ground;" the required drawing "is then made with a pointed instrument;" the surface thus prepared is "put into communication with the copper or negative end of a voltaic arrangement," and placed in a vessel containing a suitable solution opposite to a "conducting surface," "which communicates with the zinc or positive end" of the battery. "During the process the engraved plate may be withdrawn and examined," and, if necessary, replaced. "When some of the lines are required to be fainter than others, such parts of the design may be stopped out." Or the etching may be done in one vessel, by connecting the prepared surface with a surface electro-negative to it in a suitable solution. Or the prepared plate may be placed "in a solution between the plates forming the poles or ends of the voltaic apparatus."

A.D. 1840, October 15.—No. 8663.—Pinkus, Henry.—The title of this invention is, "An improved method of combining and applying materials applicable to the formation or construction of roads or ways." The invention consists of:—

"Methods of combining materials so as to form foundations as bases for superstructures of roads, ways, streets, or rail or tramways, and applying to said combination fixtures so as to suit said combinations or structures to the impelling of common or improved vehicles thereon." Various modes of forming the foundation and superstructure of street and other paving stone, brick, wood, asphalt, and "artificial granite," are set forth, and the structure is called "the textile or woven pavement."

"An improved locomotive impeller" for ascending inclines on railways, applicable "to any kind of locomotive engine, whether of steam, gaso-pneumatic, or electro-magnetic." Two horizontal "adhesion wheels," affixed to the locomotive, are made to rotate with the same peripheral speed as the driving wheels, and are pressed upon the inclined sides of a centre rail laid between the ordinary rails, thus assisting "the bite or adhesion of the driving wheels of the locomotive." The motion is given to the adhesion wheels by bevil gearing connected with the crank shaft; and the pressure of the wheels on the side of the centre rail (one on one side of the rail, and one on the other side) is regulated by levers that move the bearings of the axles of the adhesion wheels, which levers are under the governance of the engine driver, by means of a handle connected by "pauls," ratchet wheels, and a right and left-handed screw to the levers.

"Self-acting" and "self-regulating indicators," for marking, printing, and recording at the station the times of trains' arrival at, departure from, and passing the said station; also for recording on the engine, whilst passing a station, "the time of departure of a preceding train."

A.D. 1840, December 17.—No. 8743.—Mabley, William Tudor.—Producing surface for "printing, embossing, or impressing," by means of "electro-metallurgy." 1st. The production of a device suitable for printing, &c., such device "constituting one perfect or connected design produced from an originally engraved or otherwise executed portion of the said design," by obtaining as many moulds in relief of the portion of the engraved design as are required to perform the complete design, placing them properly together so as to form the complete design, and electrotyping an entire plate therefrom fit for printing. Flanges, for joining the moulds together, may be obtained on the moulds by fixing bars on the original design and depositing partly on them. 2nd. A mode of joining together printing plates, by electro-depositing metal in grooves formed at the edges intended to be united, the plates being in contact. 3rd. A method of "obtaining an extended surface to an engraved plate" by taking a mould of it, "attached thereto, as described above, a plain metallic or other surface," and then electrotyping the whole. 4th. A method "of producing suitable surfaces as aforesaid," by taking "a flat metal surface," coating it with wax or other easily removeable composition, tracing the design thereon, removing those portions thereof down to the metallic plate that are required to print, rubbing over this a conductor of electricity, and electro-precipitating metal thereon. The application of this method to a cylinder is also given, and plans are described in which a lithographic or other stone or soft metal is used to form the design upon. 5th. The removing from moulds of plates or blocks portions of the design thereon, in order to produce plates or blocks suitable for printing in various colours. Electrotype copies are obtained from the moulds, so that each copy contains only a portion of the design to be printed in one colour. 6th. Dies for embossing horn buttons. Electrotype copies of an original mould or die are taken, and mounted in blocks for use; various ways of mounting them are described, and a method of electrotyping die blocks from a mounted block, from wax moulds, and from buttons themselves. 7th. Various modes of mounting seals, bookbinders' tools, &c., by causing the electrotype to attach itself to the holder "in the act of depositing." 8th. Setting up moulds of portions of seals and producing perfect seals from them by electro-deposition. Various applications relating to initials, &c., are described.

PHOTOGRAPHY AND MAGNESIUM.—To Mr. Brothers of Manchester clearly belongs the credit of being the first to apply the magnesium light to photograghy, and above all, to turn the application to practical account. We observe that he advertises this week in the *Manchester Guardian*, that he has now "completed arrangements for taking portraits and copies by means of the magnesium light, *in all weathers*," and that there is "an exhibition of specimens at his rooms in St. Ann's Square." The advertisement is noteworthy as a precursor of a new development in photographic art. In an article on photography in the current *Quarterly Review*, the writer thus expatiates on some of the advantages incident to the new light:—"The new magnesium light promises to dispense with the necessity of a glass studio, with all its discomfort for the sitter, and all the temptations to meretricious decoration which it appears to hold out to the photographer. The metal magnesium, the oxide and carbonate of which is a familiar medicine, is itself rare. It will burn like a candle, and it emits a light peculiar for its wonderful riches in chemical rays; but, until recently, the cost of isolating it has been so great, that its capabilities have never advanced beyond the rank of a chemical curiosity. Recent discoveries have, however, facilitated its manufacture, and it has come into partial use among photographers. A negative of Sir Charles Lyell was taken with it at the recent meeting of the British Association. A slight further reduction in cost will enable photographers to use it for the purpose of taking likenesses in the houses of their sitters; and the sitters' gain in personal comfort will be duly registered in the improved expression of the picture."

PREVENTION OF DECAY AND OXIDATION IN SHIPS.*

As the prevention of decay in the timbers of wooden-built ships, and the fouling and oxidation of the plates of iron ships, have received considerable attention from the Admiralty and merchant shipowners, the following *resumé* of all the specifications at the Patent Office bearing on this subject is given :—

Dipping timber in boiled oil is a very ancient practice, and it would be difficult to trace its origin. In 1739 Alexander Emerton took out the first recorded patent for preserving wood from decay. He prepared the planks or boards with boiling oil in the then old way, and afterwards coated them with compounded poisons, powdered glass, and sand, cemented with painting colours and oils, laid on as paint. The next patent, which was for preserving copper, or plates of which copper is a basis, was granted in 1790, to Collins & Wyatt. They covered the plates with lead or tin. In the earlier part of the present century several chemists recommended decoctions, in the form of vegetable poisons, for saturating timber, and thus destroying all animal life in the green wood. None of these poisonous solutions seem to have succeeded, for, had they been found efficacious, their application would have been continued. There was then an interval, during which the stoppage of decay seems to have been abandoned, and dry rot allowed to take its course. In 1822, John Oxford secured a patent, whereby he undertook to prevent oxidation or decay in iron or wood, by preparing tar in such a manner as to stop the evaporation of the oil contained therein, saturating it also with chlorine gas. This purified oil is then mixed with 100 parts of white lead—or of red oxide—25 parts of carbonate of lime, and 25 parts of purified coal tar added to the oil of tar. These ingredients are then applied as a paint. In the first days of iron in ship-building, rust was found to be a drawback to its general introduction. Scientific men saw the disadvantage, and sought to remedy the defect. Galvanic action, it was considered, would set all right, and the earliest patent in this direction was taken out by G. G. Bompass, in 1830. He sought to preserve metals from corrosion by an electric or galvanic process For copper to be protected in sea-water he attaches an alloy of 9 to 10 parts of zinc with 100 parts of copper. In protecting iron he employed an alloy of tin consisting of from 10 to 150 parts of tin combined with one of zinc. Following in the footsteps of Mr. Bompass, in the same year, Mr. John Revere patented an invention for fixing zinc protectors to the brace or stud of chain cables, and other iron surfaces exposed to the action of salt water. These galvanic zinc protectors were riveted or soldered on according to requirement. It is known that one of the most distinguished of our electricians is in favour of inserting strips of zinc in the plates of ships; but if this principle proved correct in practice, it would long since have been universally adopted. Zinc plays an important part in patents for the prevention of oxidation. In 1837 Jacob Perkins got protection for a plan of coating copper tubes of boilers with a preparation consisting of two-thirds of zinc with one-third of copper; but he had been preceded in 1832 by Captain H. W. Craufurd, R.N., who proposed to preserve copper and iron from oxidation by coating with zinc paint in a fused state. Over this he laid a second covering of pure tin, or tin alloyed with lead. Captain Craufurd explains in detail his method of compounding the ingredients. In 1838, Le Comte de Fontainemoreau, considering Captain Craufurd's mode of fixing or adapting the zinc to this purpose as erroneous, applied for a patent of a more comprehensive description, for applying the zinc coating to metals. Again, in 1839, Mr. Thomas Dowling patented what he terms a conservative bath, applied to metals after grinding. He describes the machinery by which he effects this, the chief of which is a zinc wheel and galvanic vapour furnace.

In 1840, Mr. J. R. Neilson came forward with his invention for the application of a coating of copper, or copper alloyed with zinc or tin, or both, to the surface of iron. This was done by covering the mould to be cast with the material. In malleable iron, dried borax or flux is spread over the iron, which is then prepared with alloy heated to a temperature sufficient to melt copper, and, in its heated state, plunged into cold water to detach the scale of oxide. Mr Arthur Wall likewise, in 1840, mixed 20 pounds of the strongest muriatic acid diluted with three gallons of water, then added 12 pounds of steel or wrought iron filings. The filings were heated to redness before mixture. The whole was then subjected to heating in a pan, &c., and the composition was then applied to prevent corrosion. In 1841, Mr. W. E. Newton employed silicates of potash, or soda, for making a plaster or coating to prevent iron from becoming rusty. After him came Professor R. Mallet, engineer, of Dublin, whose varied processes are of the most complex character. Finding that iron covered with zinc, when immersed in sea-water, and certain fresh waters, gathered to itself a coating of carbonate of lime, destructive to the protective power of the zinc, and affording a surface for the attachment and growth of marine animals of the molluscous and testaceous classes, and aquatic plants, he applied chemical means to detach the scales of oxide from iron, and then plunged it into a preparing bath. After undergoing a series of processes, the metal is coated with an alloy or zoofagous paint, which paint is rendered poisonous by admixture of salts of metals, by means of which he sought to render the zinc effective as an anti-corrosive protector. In 1841, also, Mr. E. Morewood endeavoured to preserve iron from oxidation or rust by tinning it, and then dipping the tin covering or surface in molten zinc. Moses Poole, in 1845, claimed to possess an invention whereby he rendered iron more hard and durable, and free from oxidation, by the use of ferrocyanide of sodium, calcium, barium, or any other alkali, or alkaline earthy base; to be used in a manner fully set forth in his specification. In 1846, Mr. Andrew Smith improved upon the plans for melting the zinc. He employed a bath of lead or tin, or any composition or medium that melts at a lower degree of heat than zinc, by which means the heat from the fire of the furnace is taken up and transmitted to the receptacle containing the zinc for melting. Baron Wetterstedt, in 1846, added the regulus of antimony to lead sheets, combined copper with antimony, made sheet metal by using lead and tin, and lastly, protected metals by paints thus prepared :—1st. One part of regulus of antimony to three parts of copper, mixed, melted together, run out into water, and then heated gently. Two parts of oxide of copper are added, and moistened with naphtha. The whole is then added to a composition of tar and naphtha. 2nd. Another paint is compounded of 30 lbs. of tar, 30 lbs. of pitch, 20 lbs. of dried soot, 4 lbs. of tallow from sperm oil, and naphtha added for consistency.

Mr. C. H. Paris, in 1849, coated metals with glass or vitreous matter. The metal went through a cleansing process. Gum water is then applied, and over this the dry or powdered glass is shaken, and then fused by heat till a glass surface is formed. Mr. Paris claimed the application of carbonate of soda for applying glass in this manner. Mr. J. MacIntosh, in 1852, made a paint from decomposed india-rubber in combination with oils or fatty matter, saponified by metallic salts, with lime for thickening the liquid. For bottoms of ships he recommends the india-rubber, when in a fluid state, to be combined with metallic soap, thickened with lime and coloured by pigments. Messrs. Hughes and Firmin, in 1852, manufactured lamp black from the vapour of coal tar, dead oil, dead oil salts, coal pitch, naphtha, linseed oil, and other materials. From the products a fuel is produced, and this residue has by another inventor been mixed with oils, ground and made into a paint. In 1852, also, Mr. R. M. Glover took out a patent for a preparation of arsenite of lead and arsenite of copper, and the red and yellow sulphurets of arsenic. The proportion of each were as follows :—Two parts, by weight, of arsenite of lead, one of realgar, one of orpiment, and one of arsenite of copper. In the same year, Mr. J. Murdock invented a variety of driers for zinc when the white of zinc is employed instead of white lead. The protoxides are manganese, cobalt, iron, tin, and nickel; for acids, the benzoic, urobenzoic, and the boric. In 1852, Mr. Binks patented a substitute for linseed or drying oils, in the products derived from dissolving what are called insoluble soaps. A pigment is then ground in this solution, and the paint is ready for application, The pigment may be white lead, oxide of zinc, lamp black, or any other. J. C. Medeiros, in 1853, proposed the use of mercury or quicksilver on iron plates for sheathing ships. The salts of mercury are dissolved, then a bath is formed, and the plates allowed to remain in the solution till their surface is equally and regularly amalgamated.

Mr. Newton, in 1854, made a paint from ground plumbago, pulverized charcoal, and the black soot formed by the burning of bituminous matter, along with ivory black, or bone or lamp black. Mr. Ryder also, in 1854, described a method for mixing gutta-percha with common resin, or tar, pitch, or asphaltum, dissolving them in impure benzole or coal naphtha. Mr. Newton took out a second patent, in 1854, for the production of a siccative black, brown, or grey pigment or colouring matter, by the admixture with the gas tar, or other organic substance to be carbonized for the purpose, of the oxides of potassium, sodium, calcium, aluminum, or other alkaline or earthy bases for paints. Mr. F. Ransome, 1854, patented a mixture, consisting of ground oxides and carbonates

* From the Journal of the Society of Arts.

of lead or zinc, and carbonate or sulphate of barytes with soluble silica. Mr. J. Rogers, in 1855, to prevent oxidation, deoxidizes metallic ores by a revolving cylinder, fitted with helical or screw-formed divisions to receive the ores in a pulverized state, and then submits the same to heat, and constant agitation by the revolution of the cylinder. Mr. B. Rosenburg, in 1855, manufactured a paint as follows:—100 lbs. of triturated white lead, 2¼ gallons of copal varnish, 1½ gallons of spirits of turpentine, 1½ gallons of linseed oil, and, for colouring, a small quantity of red lead. Before the metal is painted it is subjected to the fire for cleansing, and when cool the preparation is applied, then varnished with copal, and dried by a hot air process. Mr. J. E. Cook, in 1855, proposed a composition consisting of gum shellac, dissolved in methylated spirit or in wood spirit. In 1856, the patent of Messrs. Bancroft & White claims the manufacture of oils from petroleum, for preserving metals and ships' sheathing. Mr. A. F. Mennons, in 1856, obtained a patent for a non-conducting and inoxidable composition for metals, made thus:—

Argillaceous clays, containing a certain proportion of alumina	100 parts.
Oily substances and residues	6 "
Oil sediment	5 "
Fat	2 "
Animal charcoal	2 "
Mucilaginous substances, such as glue, &c.	2 "
Wood sawdust, already employed in the purification of oils in the process of dyeing	10 "
Waste hair well beaten	4 "

To the preceding materials a decoction of logwood and soot is added.

Mr. J. M'Innes, in 1856, was granted a patent for coating metals with powdered emery stone mixed with a varnish of shellac dissolved in spirits of wine, with the addition of castor oil. As emery contains 87 per cent. of aluminium, Mr. M'Innes considered that this paint would be solid enough to resist all action in the water, and never decompose. Mr. R. D. Atkinson, of Hull, in 1856, invented a plan for coating and protecting metals from oxidation, by depositing copper or brass upon surfaces of prepared iron, the deposit to be melted in conjunction with carbonic acid gas, the coating to be put on by a brush, or through the medium of galvanism. Depositing brass on iron is now being successfully carried out at Portsmouth, by Mr. Wielan, on armour plates and other iron surfaces. Mr. A. Reid, mineralogist, in 1856, describes in his specification what he deems a sure way of preventing oxidation. He places the iron in a properly constructed furnace, then covers the metal with soot, or other matters possessing the like element, the temperature is then raised to red or white heat, and continued for half an hour, or according to the size of the iron operated upon. It is then suffered to cool, the surface is cleaned, and Mr Reid asserts that a coat impervious to rust is formed. If this is verified by positive experiments, the cheapness and simplicity of the plan deserves to be widely known. Mr. Joseph Poleux, of New York, communicates, in the same year, a plan to overcome oxidation. He employs muriatic acid, nitric, or sulphine acid, of the ordinary degrees of concentration in commerce, without dilution combined with the introduction of spelter into the cleansing process. In 1857, Mr. G. Bedson patented a new process He melts a quantity of pitch derived from mineral tar, and a proportion of tar oil, with caoutchouc tempered with tar oil and shellac, the substance to be solid and elastic when cold. Mr. C. F. L. Oudry claims depositing copper on a preservative or intermediate coating instead of on the metal. He deposits copper in a pure state to any thickness on all metals. Mr. C Iles, in 1857, describes a means of applying earthy cements to metals. In 1858, Mr. J. Coutts received a patent for applying the following pigment by heated air:—

Carbonate of baryta	·650
Litharge	·065
Arsenious acid	·030
Asphaltum	·050
Oxide of calcium	·030
Creosote (oil of tar)	·175

Perhaps the most novel introduction is that patented here by Messrs. Bouchard & Clavel, the Paris bankers, in 1858. On the estate of La Gruerié, in Charney, Department of Yonne, France, is found an earth of the ochre description, called "Burgundy Red." This earth contains most valuable properties, and is said to be an exceedingly good preservative against rust. It is used as a cement and paint by admixture with the following:—

Burgundy red	66 parts.
Grease of oil	15 "
Lime	11 "
Unburnt earthenware, chalk, or Roman cement	8 "
	100 "

This is said to prevent oxidation if the earth is merely diluted with volatile oil. D M'Crae, in 1858, was allowed a patent for preserving bottoms of ships from fouling or decay. He applies grease from the cells of boiled bones, kitchen-stuff, and butter without salt; a poisonous matter is mixed with these fatty substances. Mr G. P. Lock, in 1858, made a composition for the under coating of iron ships, made from iron ore ground in boiled linseed oil 50 per cent., oil of turpentine 50 per cent., well mixed. For the outer coatings, white lead 40 per cent., blue mineral or copperas 10 per cent., and oil of turpentine 50 per cent. In 1859, Mr. Henry, on the part of Moisant & Co., sought protection for bituminous products and compounds of bitumen for preventing oxidation. Mr. T. J. Labelle made a preparation of caoutchouc paints and colours for vulcanizing. Mr. J. Crawford, of Liverpool, in 1859, applied for a patent for a metallic paint or varnish, composed of plumbago, or black lead, fine or gum varnish, arsenic, and spirits of turpentine mixed. Mr. F. W. Emerson, in 1859, prepared an anti-corrosive paint from oxi-chloride of lead, mixed and ground with oil, turpentine, varnish, or other vehicle. Mr. Weild, in 1859, sought to economise time and labour, by a mechanical machine for applying paints to metals on large surfaces. Mr. James Meikle, in 1859, proposed coating iron ships with asphalte, In the same year M. Auguste Pin dissolved sugar in muriate of zinc, then added wax and soap, in which was incorporated calcareous stones, phosphate of soda, sulphate of zinc, and copper, and the syrup of potatoes or sugar, with powdered marble, quartz, or felspar.

In 1859, Mr. F. G. Spilsbury, of Louvain, applied for a patent for the manufacture of a paint. He took sulphate of lead, and heated it to a red heat, either by itself or mixed with alumina or other earths; the pigment thus obtained to be washed first with sulphuric acid, then with water, when it is finally dried. Previous to drying the pigments are digested with salts of tungstic acid, molybdic acid, titanic acid, tantalic acid, arsenic acid, acid of antimony, or other metallic acid, or with mixture of the above salts. A combination between the sulphate of lead and the metallic acid or acids is obtained, and the resulting pigments are dried in like manner after having been cleared from all adhering salts. The pigments may then be mixed with oil and used as a substitute for white lead. Mr. J F. J. Lecocq, in 1860, prepared a calcareous varnish for coating iron and the bottoms of ships. Mr. H. Kemp, in 1860, patented a composition consisting of peat tar, wood tar, methylated spirit, peat oil, or linseed oil, arsenic, resin, and carburet of iron, for preserving ships' bottoms. Mr. Allen's plan for making a coating or anti-corrosive paint for metals is thus given:—Ammoniacal liquid obtained from coal tar, or gas tar, prevents incrustation in boilers, and is applicable to painting the inside plates. Messrs. Pile & Smyth, of West Hartlepool, took out a patent in 1860. They employ a red composition and enamel, consisting of a combination of litharge, Venetian red, and pine varnish. Over this composition is applied a coating of resin, gums, or any pitch or bituminous substance, with the addition of coal tar or oil This is put on in a hot lava state, and the process is called enameling. An impermeable oil varnish was patented by M. Antoine Bonet, in 1860, composed of 100 parts of alcohol, 100 parts of spirits of turpentine, one part of sulphuric ether, and one of carbonate of soda.

Mr. Robert Smith, shipowner, of Finsbury, applied to the Patent Office, in 1860, to protect his system for keeping vessels from fouling and worming. He applies equal parts of pitch, tar, resin, and turpentine, with any other adhesive compound. Assafœtida to be mixed with the foregoing, as a poison to destroy life. When the coating is laid on, and dry, the whole to be covered with paper or cloth. Mr. G. Hallet, in 1860, in his patent explains his method of protecting metal. He grinds the oxide of antimony to powder, then dries it, and mixes with it 12 lbs. of linseed oil to the hundredweight of powdered oxide. Mr. Richardson, in 1861, to prevent oxidation, would cover the metal with vulcanized india-rubber, cloth, or gutta-percha, the object sought being to provide for unequal expansion of the metal and coating. Mr. Francis Pulz, chemist, 1861, causes oxygen to be passed through sulphuric acid, to render the oxygen more active as an oxidizing agent, as it combines, when so treated, with other substances for which it has an affinity, for manufacturing purposes. Mr. Pulz also, in a second patent, submits oily matters to this oxidizing agency, by causing the sulphureted gas to pass through them when in a liquid state. Mr. Martin Miller sends a communication, in 1861, for coating metals by metals or alloys in different ways. Mr. John Hay, in 1861, patented a drying oil. He lays a non-conducting coat, and then makes a paint by grinding in linseed oil the black or protoxide

of copper, which is then boiled till reduced to the sub-oxide, and by thus oxygenating the oil he claims to have formed a quick drying cupreous oil. Mr. John Snider, of the United States, patented here a compound, in 1861, for coating metals. He reduces amorphous graphite to fine powder, and then mixes it with ore by the agency of a heated steam-pipe. When cool and dry, one pound of oil is added to three pounds of the powder, and when the ingredients are combined, hot pure bees'-wax, in the proportion of one pound of wax to ten pounds of graphite, is mixed. Afterwards linseed oil may be added. Mr. Snider details his manner of manipulating and preparing the graphite and ore. Messrs. Hallet and Stenhouse, in 1861, obtained a patent for the manufacture of pigments for coating surfaces. They employ native oxide of antimony, chemically treated in ways too intricate for explanation in this abbreviated outline, and mixed with red lead or litharge. They sometimes take type metal or worn-out types, reduce them to a coarse powder, and then mix them with their own weight of zinc, and calcine them. This produces a yellow pigment.

INDIAN TELEGRAPHS.

The following letter, addressed by the Secretary of the Kurrachee Chamber of Commerce to the Secretary to Government at Bombay, in answer to a communication from the latter official inquiry whether the working of the telegraph had improved during the past twelve months, has been published by the Committee of the Kurrachee Chamber of Commerce :—

Chamber of Commerce, Kurrachee, May 17, 1864.

Sir,—I have the honour to acknowledge the receipt of your letter, No. 846, of 1864, requesting the opinion of the Chamber of Commerce as to whether "the working of the telegraph department has, during the last twelve months, improved."

Previous to the receipt of your letter under reply, it had been resolved by the managing committee of the Chamber to memorialize the Governor-General in Council upon the present disgraceful state of the telegraph line between Kurrachee and Bombay, and its almost total inefficiency for commercial purposes. This fact will show you that no improvement has taken place, and in the opinion of the Chamber the line is at present, so far as can be judged by results, in a worse state than before. Interruptions are not, perhaps, more frequent, but the time occupied in transit is generally so long, and always so uncertain, that the advantages usually derivable from telegraphic communication are quite neutralized. It is impossible to calculate with any approach to certainty how long it may take to send a message to Bombay, or within what time an answer may be expected. As a case in point, I may mention that telegrams of the 6th and 9th instants were received here on the 10th, and of the 7th and 9th on the following day, and irregularities of this kind are of constant occurrence. In addition to this, commercial messages are frequently so mangled as to be not only perfectly useless, but liable to cause serious loss and inconvenience by misleading the recipients on matters of mercantile importance. So gross are these mistakes, that it is hardly safe to embark in any commercial transaction upon the faith of telegrams received from Bombay, and instances could be named in which merchants here have been subjected to pecuniary loss by making their calculations upon quotations contained in Bombay telegrams.

In the opinion of the Chamber of Commerce most, if not all, of these evils are caused by the single line of wire between Kurrachee and Bombay being totally insufficient for the work it is required to perform ; and this evil they believe to be aggravated by the system of centralization under which the department is managed, and which, as they are informed, involves a reference to Calcutta, and consequent delay, before undertaking the most simple necessary repairs. In order to maintain efficient communication with Bombay, a double line or submarine cable is absolutely essential, and it is believed that even this will not meet the object in view without a thorough reorganization of the department, involving an abolition of the centralization system, a much more liberal scale of expenditure for maintenance and establishments, and a transference of the superintendence of the lines from a distant official in Calcutta to the local Governments, and to well paid and responsible subordinates.

The Chamber desire especially to draw the attention of the Government of Bombay to the fact that telegraphic communication with England, viâ the Euphrates valley, is now nearly established, and that as soon as this line is completed, messages of the utmost importance may be expected to arrive daily in Kurrachee. The line from this place to Bombay is even now overburdened, and all but useless, and the Chamber leave you to imagine what the result will be when a vast mass of official and private telegrams of English news require to be transmitted in addition to the existing traffic.—

I have, &c., (Signed) H. Jacob, Secretary.

A. D. Robertson, Esq., Secretary to Government, Bombay.

Telegraph Clerks' Provident Fund.—The Most Noble the Marquis of Townshend has, we understand, consented to become the president of this promising institution.

GALVANIZING IRON.

The processes of galvanizing iron (in sheet and in wire) are but little understood. In order, therefore, to disseminate useful information on this subject, we herewith append an account of the various operations necessary to be performed to effect the coating of iron with zinc, for which we are indebted to the supplement of "Ure's Dictionary of the Arts and Sciences":—

In 1837, Mr. H. W. Crawford patented a process for zincing iron. In the "Repertory of Patent Inventions," his process is thus described :—Sheet-iron, iron castings, and various other objects in iron, are cleaned and scoured by immersion in a bath of water acidulated with sulphuric acid, heated in a leaden vessel, or used cold in one of wood, just to remove the oxide. They are then thrown into cold water, and taken out one at a time to be scoured with sand and water with a piece of cork, or more usually with a piece of the husk of the cocoa-nut, the ends of the fibres of which serve as a brush, and the plates are afterwards thrown into cold water.

Pure zinc, covered with a thick layer of sal ammoniac, is then melted in a bath, and the iron, if in sheets, is dipped several sheets at a time in a cradle or grating. The sheets are slowly raised to allow the superfluous zinc to drain off, and are thrown whilst hot into cold water, on removal from which they only require to be wiped dry.

Thick pieces are heated, before immersion, in a reverberatory furnace, to avoid cooling the zinc. Chains are similarly treated, and on removal from the zinc require to be shaken until cold, to avoid the links being soldered together. Nails and small articles are dipped in muriatic acid and dried in a reverberatory furnace, and then thrown all together in the zinc, covered with the sal ammoniac, left for one minute, and taken out slowly with an iron skimmer. They come out in a mass, soldered together, and for their separation are afterwards placed in a crucible and surrounded with charcoal powder, then heated to redness and shaken about until cold, for their separation. Wire is reeled through the zinc, into which it is compelled to dip by a fork or other contrivance. It will be understood that the zinc is melted with a thick coat of sal ammoniac to prevent the loss of zinc by oxidation.

Mr. Mallett coated iron with zinc by the following process :—The plates are immersed in a cleansing bath of equal parts of sulphuric or muriatic acid and water, used warm ; the works are then hammered and scrubbed with emery and sand to detach the scales, and to thoroughly clean them ; they are then immersed in a "preparing bath" of equal parts of saturated solutions of muriate of zinc and sal ammoniac, from which the works are transferred to a fluid metallic bath, consisting of 202 parts of mercury and 1,292 parts of zinc, both by weight, to every ton weight of which alloy is added above one pound of either potassium or sodium, the latter being preferred. As soon as the cleaned iron works have attained the melting heat of the triple alloy, they are removed, having become thoroughly coated with zinc. At the proper fusing temperature of this alloy, which is about 680° Fahr., it will dissolve a plate of wrought-iron of an eighth of an inch thick in a few seconds.

Morewood and Rogers's galvanized tinned iron is prepared under several patents. Their process is as follows :—The sheets are pickled, scoured, and cleaned, just the same as for ordinary tinning. A large wooden bath is then half filled with a dilute solution of muriate of tin, prepared by dissolving metallic tin by concentrated muriatic acid, which requires a period of two or three days. Two quarts of the saturated solution are added to 300 or 400 gallons of the water contained in the bath. Over the bottom of the bath is first spread a thin layer of finely-granulated zinc, then a cleaned iron plate, and so on, a layer of granulated zinc and a cleaned iron plate alternately, until the bath is full. The zinc and iron, together with the fluid, constitute a weak galvanic battery, and the tin is deposited from the solution so as to coat the iron with a dull uniform layer of metallic tin in about two hours. The tinned iron is then passed through a bath containing fluid zinc, covered with sal ammoniac mixed with earthy matter, to lessen the volatillization of the sal ammoniac, which becomes as fluid as treacle. Two iron rollers immersed below the surface of the zinc, are fixed to the bath, and are driven by machinery to carry the plates through the fluid metal at any velocity previously determined. The plates are received one by one from the tinning bath, drained for a short time, and passed at once, whilst still wet, by means of the rollers, through the bath, as described. The plates take up a very regular and smooth layer of zinc, which, owing to the presence of the the tin beneath, assumes its natural crystalline character, giving the plates an appearance resembling that known as the *moirec metallique*.

It is stated that galvanized iron plates, cut with shears so as to expose the central iron, become zinced round the edges, and at the holes where the nails were driven. We are also informed that *ungalvanized iron* will, if moist when near galvanized plate, become zinced, and that telegraph wires, where cut through, become coated by the action of the rain water on the galvanized portion of the surfaces.

It has been stated that the galvanized iron is not more durable than unprotected iron ; that, indeed, where the zinc is by any accident removed, the destruction is more rapid than ordinary. We have made especial inquiries, and find that in forges where there is any escape of sulphur vapour the galvanized iron does not stand well, but that under all ordinary circumstances it has the merit of great durability in addition to its other good qualities.

TELEGRAPHIC NEWS.

THE TELEGRAPH IN RUSSIA.—Intelligence has just been received of the opening of the telegraph line from Irkutsk to Kiachta. News may now be sent to Pekin in four days' less time than formerly by the ordinary post.

TELEGRAPHIC PROGRESS ON THE CONTINENT.—The Austro-Germanic Telegraphic Union included on the 1st January, 1864, 981 stations, distributed over an extent of 5,205 geographical miles. This is an increase of 226 stations and 710 miles of telegraphic line over 1863.

THOMPSON'S ELECTRO-MAGNETIC INDUCTION MACHINE.—We have on several occasions adverted to Mr. Thompson's valuable invention for obtaining currents of electricity of any required electro-motive force from a battery of small electro-motive power. The advantages of this machine have been recognised by the eminent electro-plating firm of Elkington, Birmingham, who are, we believe, about to introduce it into their manufacturing establishment. The electro-magnetic induction machine is applicable to a variety of purposes, for particulars of which we refer our readers to another part of this journal.

THE TELEGRAPH FROM RED RIVER TO NEW WESTMINSTER.—Notice has been given in the British Columbian *Gazette*, that Dr. Rae was expected in that colony by way of the Rocky Mountains, completing his survey of the proposed line of telegraph, and that the Governor requested all magistrates and other public officers to furnish him with such aid and assistance as he might require. Accounts from the mine districts state that Dr. Rae has arrived at the mouth of the Quesnelle, having come down the Frazer from Fort George in a canoe with one Indian.

THE CYCLONE AT CALCUTTA.—Mr. C. B. Ransom, master of the ship Sophia Joakim, writing from Calcutta on the 6th ult., says:—"All the telegraph wires are deranged, so that we have no information of the effects of the storm on vessels at the Sandheads; but as the centre of the cyclone passed to the southward of Calcutta, we fear that the hurricane was felt severely at the Sandheads and at the head of the Bay of Bengal." The agents for Lloyd's, at Calcutta, under the same date as the foregoing letter, write:—"The telegraph wires have been destroyed, and since the occurrence of the tempest there has been no communication with any of the river stations."

LOSS AND RECOVERY OF £1,000.—On Monday last, while a merchant was passing along the passage leading from the Exchange to St. Vincent-place, Glasgow, he dropped a parcel containing £1,000—ten £100 notes of the Union Bank. Immediately thereafter a lad named Cunningham, a clerk in the Magnetic Telegraph Company's office, found the notes at the foot of the stairs leading to the superintendent's department, and at once handed them to his superior, who, on discovering that the notes belonged to the Union Bank, proceeded hither, and handed them over to the secretary. In a short time afterwards the merchant entered the bank to make known his loss, but was gratified to receive his cash. On hearing who the finder was, he proceeded to the telegraph office, and presented the lad Cunningham with £100.

THE INDO-EUROPEAN TELEGRAPH.—The *Bombay Gazette* of the 14th October contains the following:—A telegram, dated 27th September, has been received by the Governor of Bombay from Major Champain, director of the Persian telegraph, from Teheran, which occupied only 16 hours and 21 minutes in its transmission from the Persian capital to Dapooree, announcing the completion of the telegraph from Bushire to Teheran. The line to Bagdad would, it was expected, be completed in ten days from the above date; but it cannot be worked until the dispute between the Turks and Persians regarding the frontier has been settled. Messages can now be sent from Bushire to Shiraz, Ispahan, and Teheran, and to all parts of India by the submarine telegraph through Kurrachee. Communication between Kurrachee and Bussorah is now perfect—from Kurrachee to Gwadur by aerial telegraph, and thence to Fao by submarine cable. The two breaks in the cable between Kurrachee and Gwadur will be shortly repaired.

GREAT INUNDATION IN ITALY.—By a telegram from Turin, dated the 9th November, we learn that serious damage has been caused in Tuscany by heavy rains. The floods have broken up the railway lines at several points, thereby destroying the communication between Empoli, Siena, Macchia, and Pistoja. Between the latter place and Bologna, the Arno has burst its embankment, overthrown the telegraph poles, and swept away the works which were in course of construction. The latest despatches state that the lower parts of Florence are inundated, and that the Arno has risen to the level of the parapets of the quays. The above news, despatched from Florence on the 6th inst., only reached Turin to-day, in consequence of the interruption of the telegraphic communication. News of a more satisfactory character has been received this afternoon.

ATLANTIC TELEGRAPH CABLE.—We are given to understand that the manufacture of this cable is proceeding very rapidly. One of the Government tugs, acting as tender to the Great Eastern, lies off Morden Wharf ready to receive on board 300 miles now completely sheathed and ready for coiling in the tanks which have been fitted in the hold of the great ship for the purpose. Some experiments have recently been made to test the strength and ductility of the cable, the results of which are of a very satisfactory nature. A given length was taken, suspended, and gradually weighted until it broke, the elongations succeeding each additional weighting being duly registered. The cable selected bore the weight of six three-fifth tons. The case, the spiral wires involving it, the insulating body, the jute yarn, and each separate strand of the cable were similarly tested. It was found from those experiments that the more the fibres of wire were brought into a state of tension, the greater became its strength, and that as an insulator gutta percha, although not so perfect as india-rubber, is far more durable, and that the cable as now manufactured will be able to bear a strain four times its own weight when laid at the bottom of the Atlantic.

THE UNITED KINGDOM ELECTRIC TELEGRAPH COMPANY.—"D. W." writes a contemporary in the following strain:—"We have, as you well know, rival companies of all kinds and descriptions, and of the number are telegraph companies. These latter profess to transmit messages for the public, at certain charges, with all possible speed; and the public cannot be considered unreasonable in expecting that the promises will be faithfully performed, especially as telegraphic messages are most generally of the greatest importance. I regret that I should have found that it will be quite necessary soon to have some legislative measure passed to compel these companies to perform the duties they undertake with greater regularity and certainty than they do at present, as the following case will, I think, clearly prove. I had occasion on Saturday, the 22nd of October, to send a message from Northumberland to Gloucestershire, calling to the bedside of a poor dying clergyman his brother. The message in question (written in the most urgent words that could be employed) was sent to the nearest station of the United Kingdom Electric Telegraph Company, between five and six P.M. It could not be sent just at the time, as other messages were being transmitted; but I shall, I am afraid, hardly be believed when I state that the clerk never forwarded the message at all, notwithstanding its very urgent nature, and gave no notice of his having neglected to send it until the following Monday at noon! The poor sufferer (whose illness came on very suddenly) breathed his last on Sunday afternoon, without having seen his relative; and it has now been found that it was of the greatest importance that the desire of this poor man to see his brother should have been gratified. It was, however, denied to him through the unpardonable (as I think) negligence of the officials of this very badly conducted telegraphic company. Pray allow space, if possible, for this simple statement of facts in your all-powerful journal, in the hope of preventing similar neglect of duty."

TELEGRAPHIC COMMUNICATION WITH BOMBAY.—By letters just received from Teheran we learn that Major Champain, R.E. (the officer employed in the construction of the Persian lines) was on the 29th of September last in direct communication with Bombay by means of the line constructed by himself from Teheran to Bushire, and of the submarine cable laid down by his chief, Lieut.-Col. Stewart, from Bushire to Kurrachee and Bombay, the distance from Teheran to Bushire being 700 miles. The time occupied in transmitting the first message from Teheran to Bombay was less than four hours and a half. Major Champain has also finished the line from Bagdad to Teheran with the exception of about twenty miles, which is the subject of a boundary dispute between the Persian and Turkish authorities, and which, at the date of our advices, he had not been allowed to connect, although the wires were actually within a few feet of each other. However, it was Major Champain's intention to connect the finished portions of the line by horse expresses three or four times a day until the termination of the dispute. In the meantime the recently completed Russian line from St. Petersburg to Teheran (although uncertain and expensive) affords an uninterrupted telegraphic communication between London and Bombay.

TELEGRAPHY IN NEW ZEALAND.—An advertisement which appeared in our [*Colonist*] columns a few days ago, calling for tenders for the supply of 4,000 telegraph poles, to be delivered between Nelson and the southern boundary of the province, passing through the province of Marlborough, is one of those "signs of the times" which are calculated to arrest attention in no ordinary degree. Little more than twenty-two years have elapsed since the first arrival of European settlers in this island, and so rapid has been the progress of the colony, that in all human probability ere the twenty-third year has run its course, the electric telegraph—that marvellous engine which is fast converting the whole of Christendom into one vast whispering-gallery—will be in active operation from Nelson at the north extremity of the island, to Invercargill at the south, and the capitals of all the five provinces—Nelson, Marlborough, Canterbury, Otago, and Southland—will be placed in almost instant communication with each other. Already telegraphic poles have been erected from Southland to the Waitaki; throughout the whole length of the Canterbury province they are either upon the ground, or will speedily be so; and now tenders are invited to furnish the number required for the extension of the line through the provinces of Nelson and Marlborough. As the wire and all the apparatus required for the purpose are either now in the colony or on their way hither from England, the completion of the line may almost certainly be calculated upon within the time we have specified.

EXPLOSION AT THE LIVERPOOL OFFICES OF THE UNITED KINGDOM TELEGRAPH COMPANY.—On the 9th inst., about eleven o'clock in the morning, the frequenters of the "flags" were startled by a loud report, which proceeded from the basement floor of the Liverpool and London Chambers. It was soon ascertained that the cause of the disturbance was an explosion of gas at the office of the United Kingdom Electric Telegraph Company, doing damage to the extent of about £20. From about nine o'clock in the morning the officials employed in the office had noticed a smell of gas. They sent twice to the gas-office in Newington for a man to come down and inspect the meter, but, as no one came, and the gaseous fumes became stronger, a man was obtained from Mr. Holgate's, a gasfitter, in Dale Street. After trying in vain for some time to find out the place of escape, this man

went with a light to examine the meter, which stands in one corner of the front offices. An explosion of considerable violence immediately followed. The glass front of the office was completely blown out, the partitions in the office were torn from their fastenings, and removed several feet from their proper positions, and even the heavy counter was shifted. In fact, in a moment the place had become a scene of disorder. Though of course greatly alarmed, neither the man who had unwittingly caused the accident, nor the clerks in the office, received any bodily hurt beyond a few flesh cuts from the fragments of broken glass, which were sent flying about in all directions. Mr. Barrett, superintendent of the West of England Fire Brigade, who happened to be in the Liverpool and London office, on hearing the explosion immediately ran to see what was the matter. Some smoke which was issuing from the office at first led him to suppose that the fittings had been set on fire, but he soon discovered that the smoke proceeded from a fire in the office, and that, as a matter of precaution, was immediately put out. The gas was then turned off at the meter, and the floor having been taken up, it was found that the gas had escaped from a fracture in the pipe one inch long, probably caused by a nail having been driven in. The gas had made its way through the crevices in the flooring, and being heavier than the air had hung about the ground till its whereabouts was so startlingly announced upon the application of a light. The building belongs to the Liverpool and London Insurance Company, and, of course, is insured in their own office. The telegraph company is uninsured. The working of the telegraph will not be interfered with. Inspector Gardner and fireman 859 were early in attendance, and rendered all the assistance they could. Mr. Andrews, the secretary of the United Kingdom Telegraph Company, informs us that the first report of the disaster was exaggerated.

MISCELLANEA.

Meteor.—M. Beraud, in a letter read at a meeting of the Academy of Sciences, states that on September 24, when he was upon an eminence near Gouzon, not far from Limoges, a little before noon, he perceived a meteor in the direction of the south-west. It had the form of a long, vertical flame, slender at the two ends, descending with a slight inclination to the west. In another letter, M. J. de Lan Lusignan states that at the same time, while in the château of Lan, near Nogaro (Gers), he heard a sound resembling prolonged thunder, the sky being very serene, and without evidence of a storm. He went out immediately, and found several persons examining a little cloud which was passing slowly over the horizon from north to south. Some had perceived a ray resembling lightning. No doubt the thundering in a clear sky remarked on by the ancients was due to meteoric phenomena.

The Great Eastern.—The action against the Great Eastern, which had been some time pending in the Court of Admiralty, has just been brought to a close. It will be remembered that the Court of Admiralty held the Great Eastern to blame for the collision by which the Jane was sunk; but on an appeal to the Privy Council it was reversed, and both parties held to blame. The matter then went before the Registrar of the Admiralty Court, and Mr. Pritchard appeared for the Great Eastern. After hearing the parties, it was held that after deducting the claim put forth by the big ship, the Company should pay £2,000 to the owners of the Jane, and be released, each side to pay their own costs. The money was paid out of £6,000 deposited in court by the Great Ship Company, and the vessel released; and thus the long-pending suit was terminated. It is to be hoped that we have heard the last of the difficulties of the leviathan ship, and that its next voyage will prove a success.

Removal of the Great Exhibition Building.—The operations for the removal of the Great Exhibition building were resumed on Saturday the 5th instant by the Royal Engineers, under Sir J. Burgoyne, Colonel Lovell, Lieut. Knocker, and a corps of sappers and miners from Chatham. The first experiment was directed to the displacement of the great corner tower in the Cromwell-road, on the left of the grand entrance, in height about 50 feet, by 40 feet square, and 150 tons in weight, the explosive charge being from 100 lbs. to 150 lbs. of gunpowder. The fuse having been applied, and the sappers and miners having connected it with the electric wires of the battery some 200 yards away, the word of command was given by the shrill sound of a bugle, but the explosion had no perceptible effect whatever on the enormous structure, beyond making a breach in the bricks at the basement, and causing a cloud of smoke dust. A second and a third time supplemental charges of ammunition were applied, and the bugle sounded and the battery fired, but with the same result as before; the tower stood stubbornly, and it was thereupon determined to abandon that part of the experiment, and to operate on the Albert towers at the western end of the building, to which the spectators flocked. Here the apparatus of destruction was again arranged, and the bugle sounded, but no successful result was achieved until the second sound of the bugle, when suddenly one-half of the first tower came down with a tremendous crash to the ground, amid the cheers of the spectators. Attempts were made to dislodge the other half of the tower, but, as it was getting dusk and dangerous, further operations were deferred. Two causes are assigned for the failure that took place; first, the incompleteness of the electric connection with the explosive charges; and, secondly, to the explosive powers not being equivalent to the mass to be removed.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2710. R. C. Robinson, improvements in semaphoric signals applicable to railway carriages.

2712. F. J. Scott, improvements in means or apparatus for signalling between passengers and guards, or others, in railway trains.

2713. J. Walker, an improved method of making signals in carriages, particularly applicable for communicating between passengers and guards in railway trains.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2280. J. Adams, improvements in the means of communicating or signalling between the different parts of railway trains.

2486. C. H. Collette, improvements in magneto-electric machines.—A communication.

PATENT WHICH HAS BECOME VOID.

2661. T. Morris, R. Weare, and E. H. C. Monckton, improvements in magnets, induction coils, and in insulating wire and metal for electric and other purposes.

ON RAILWAY ELECTRIC SIGNALLING.

By W. H. Preece, Assoc. Inst. C.E.

(*Continued from page* 219.)

In establishing electrical signalling upon the London and South Western Railway, great precautions have been taken to eliminate every imperfection in existing instruments and to make the plan fully meet every requirement demanded of such a system. These requirements are :—

1st. A means of communication between two stations which shall give notice of the approach and departure of trains.

2nd. A "Danger" and "All clear" signal to rule and protect each line of rails.

3rd. That the man at one station shall have the sole and complete control over the signal at the other station, and that it shall be *impossible* for him to interfere with or alter the signal in his own box.

4th. That every signal shall be properly acknowledged, and that the acknowledgment shall not only imply the due receipt of the signal sent, but that it has been correctly understood and properly acted upon.

5th. That any derangement of the apparatus or the accidental delivery of a false signal, either by the man himself or by the mechanical interruptions to which the wires are liable, shall at once indicate danger and produce safety.

The main principle embodied in the above requirements is that the electric signalling shall be assimilated as nearly as possible to the out-door signalling, and that careful repetition and unmistakeable acknowledgment of everything done shall compensate for the loss of visual inspection and ocular supervision.

I will consider each point in succession, and show how they have been provided for.

The first requirement is that we shall have a means of communication between two stations—not necessarily a speaking telegraph—which shall give notice of the approach and departure of a train, its nature,—that is, whether it is passenger, or goods, express or special—and to which company it belongs, when two or more companies have running powers over the same line. Now the custom universally adopted by railway companies to distinguish trains, in addition to the particular discs and lights carried upon the buffer plank of the engine, is to blow the whistle a certain number of times when approaching a junction or station. The same system is adopted with electric signals, only in place of blowing the whistle we sound a bell. The construction of the bell used is wonderfully simple. It is shown in Fig. 1.

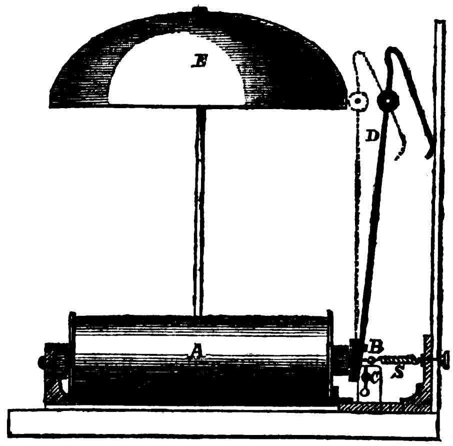

Fig. 1.

A is an ordinary electro-magnet, consisting simply of a bar of iron surrounded by a quantity of fine silk-covered copper wire, and B is a flat piece of soft iron, called an "armature," working upon the centre C, to which is attached a small rod and hammer, D. Now, whenever a current of electricity is passed through the electro-magnet, the iron bar becomes a magnet, the soft iron armature B is attracted towards it with a sharp movement, which causes the hammer D, by the elasticity of the rod, to strike the bell E, and emit the required sound.* S is an adjusting spring to return the hammer to its normal position when the current ceases to flow.

Every current of electricity transmitted through the wire produces one blow upon the bell, and by varying the number of currents sent we can form a complete code of signals. For instance :—

1 blow	Acknowledgment.†
2 blows	Passenger train.
3 "	Goods "
4 "	Special, Engine, &c.
5 "	Obstruction signal.
&c.	&c.

This code can of course be varied at pleasure to suit the different requirements of the line upon which it is fixed. Thus at Kensington station to which place four different companies send their traffic—

2 beats would represent	North Western Trains.
3 " "	Great Western.
4 " "	Brighton.
6 " "	South Western.

If it be necessary to distinguish the difference between the passenger and goods trains of those different companies it is only necessary to give the signal *once* for passenger and *twice* for goods trains. It is possible to give fifteen distinct and unmistakeable signals upon a bell by varying the number of beats and repetitions, but six or seven are ample for all the requirements of railway signalling.

These bells are made of numerous sizes and forms to suit the various localities in which they are placed. The dome G can be made to sound any note from a shrill treble to a deep bass, so that when two or more bells are fixed in the same hut they can be easily distinguished. By increasing the size and length of the wire around the electro-magnet the loudness of the sound of the blow can be similarly increased so as easily to reach a

* This is the simple principle upon which every electro-magnetic apparatus is based. A current of electricity, when passing around it, has the power of converting an iron bar temporarily into a magnet, and thereby causing it to attract or repel iron or steel.

† Given in reply to every signal sent, as an acknowledgment of its receipt.

man when he is outside his box attending to points or altering signals, even amidst the roar of passing trains or the noise of engines blowing off steam. It is customary to distinguish up trains upon a bell, as depicted in the above figure, and down bells upon a gong made of a piece of thick steel wire spirally set. The difference in the two sounds is very striking, but there are some objections to the use of gongs, which render them unpopular. They are very easily displaced out of regulation when cleaning the instrument. The sound has very little penetration—it is scarcely audible at a distance from the hut. They quickly rust from steam and damp. The men do not like them, and as a rule the opinion of the men themselves upon questions of detail of this nature is generally right and always valuable. I have had to replace many gongs with bells, and have determined to abandon their use, and substitute bells of different notes to distinguish the up and down trains, in every case where a man is not confined to his box.

The instrument employed to sound the bell, which is technically called a "key," is shown in the annexed sketch. Every depression of the button A transmits a current of electricity to the other station, and there sounds the bell or gong.

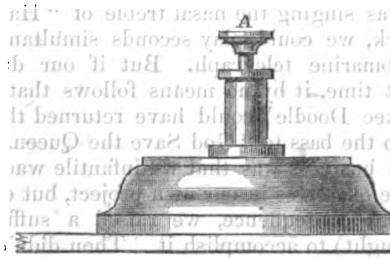

FIG. 2.

Its internal construction is shown in Fig. 3.

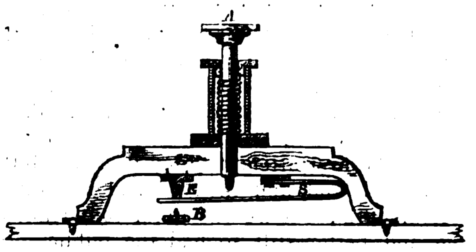

FIG. 3.

S is a spring which normally rests against the stud F, but which by the depression of the piston-rod A is brought into contact with B. The spring S is in connection with the bell-wire, and B with the battery, so that whenever S touches B a current of electricity passes which sounds the bell at the other station.

There are numerous forms of keys used upon different lines, but I prefer the one described for its strength and simplicity. Signalmen are usually very rough in handling electric apparati. A man has probably been engaged in exerting all his strength in pulling off some very distant semaphore, and enters his box hastily to give the required signal. He forgets the difference of force required to work the two instruments. He depresses the key with the same energy that he would work his out-door signals; and, unless it is made very strong, he is sure to commit damage. Any herculean signalman can exert his whole muscular energy upon these "piston-keys" or "plungers," as they are variously termed, without effecting the least injury. They are also very clean, and no dust can well enter the case, and dirty the contact points—a source of great evil in all electrical apparatus. Cleanliness and freedom from dust are essential to maintain uninterrupted working in signalling instruments, and the more this can be maintained without appealing to the care of the men by protecting the moveable parts in tight cases, the more certainty will there be in the action of the instrument. The manner in which the bell-wire works, and the bells and keys are fixed, will be fully illustrated by diagram in a subsequent number.

It will, however, be seen that in these bells we possess a perfect means of communication between two stations, by which the entry and exit of trains are clearly obtained. Bells of the above description are applicable in innumerable positions upon railways. Indeed, it may be said that wherever notice is required of the approach of a train, such as level crossings, station platforms, pointsmen's boxes, &c., they can be fixed. At every level crossing, without exception, on the South Eastern line, bells are placed in the gate-houses, which indicate to the gateman the approach of up and down trains.

There is a mechanical bell which is extensively employed upon railways, generally known as the "Bell-and-Arm," and sometimes as the "Lever-bell," which is sounded by pulling over a lever drawing a wire, like an ordinary signal, and thereby releasing a stout spring which drives the hammer against the dome with great force. They are very troublesome through the expansion and contraction of the wire from the effects of temperature. They have in several instances on the South Western line been replaced by electric bells with marked success. The men infinitely prefer them. Electric bells are not affected by temperature. They can be made loud enough for any practical purpose. They can only get out of order through carelessness, if properly constructed. Their action depends upon the battery, and if this is always kept in good order by those who have charge of its maintenance, electric bells should never fail nor ever give trouble. Bells of poor construction will of course break down, and the only remedy for this is of course to eschew such inferior articles.

As this paper is intended to be chiefly a description of the signalling apparatus as employed by me on the London and South Western Railway, I cannot enter into any description of the appliances adopted upon other lines, and in any other countries, to effect the same object. They are as numerous as they are ingenious, and would form an admirable subject for a series of papers in this Journal.

(*To be continued.*)

ELECTRO-MOTIVE FORCE IN ONE OF THE SIDES OF WHEATSTONE'S DIFFERENTIAL RESISTANCE MEASURER.

By R. S.

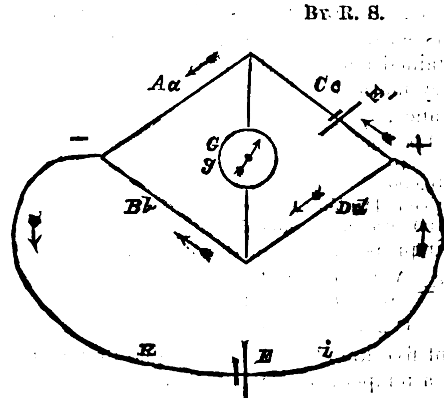

FIG. 1 represents the general plan of a Wheatstone's bridge, with an additional electro-motive force in the side, C.

Let the resistances, A, B, D, of the bridge be given, also the electro-motive forces, E and E′, and the resistance, R, of the battery circuit (—E+). It is required to find the value of the resistance, C, when the intensity, g, in the bridge, through the galvanometer $= 0$.

a, b, c, d, i, and g are the intensities.

By Kirchhoff's laws,

1) $a - c = 0$

2) $b - d = 0$

3) $iR + Dd + Bb = E$

4) $i - c - d = 0$

5) $Cc - Dd = \pm E'$

6) $Aa - Bb - Dd + Cc = \pm E'$

From 2) and 3)

$$iR + b(D + B) = E$$

and from 1) and 6)

$$c(A + C) - b(B + D) = \pm E'$$

Eliminating i and c from these equations by means of 2), 4), and 5), we have

$$R\left(\frac{\pm E' + Db}{C}\right) + b(R + D + B) = E$$

and

$$\left(\frac{\pm E' + Db}{C}\right)(A + C) - b(B + D) = \pm E'$$

The former gives the value of b,

$$b = \frac{CE \mp RE'}{R(D + C) + C(D + B)}$$

and the latter,

$$b = \pm \frac{AE'}{BC - AD}$$

Which equated against each other, and C obtained

$$C = \frac{AD}{B} \pm \frac{E'}{E} \cdot \frac{A(D + R) + B(A + R)}{B}$$

If $E' = 0$, or no electro-motive force is inserted in the side, C, of the bridge, then

$$C = \frac{AD}{B}$$

the common relation of the system of Wheatstone.

If $R = 0$ or the resistance of the battery, E, and of its connections to + and −, is inappreciable in comparison with the remaining resistances, then

$$C = \frac{AD}{B} \pm \frac{E'}{E} \cdot \frac{A(B + D)}{B}$$

and if, in addition to this, $A = B = D = n$, and $E = E'$,

$$C = n \pm 2n$$
$$= 3n, \text{ or } -n$$

Now, a resistance cannot be negative, therefore the condition of $g = 0$ can never be fulfilled when $E = E'$ at the same time that the resistances in the three sides of the bridge are equal to each other, and the currents of the batteries opposed. When, however, the currents of the batteries circulate in the same direction in the side, C, and $E = E'$, and $A = B = D = n$, as before, we must make C three times as great as either of the other sides, or, in other words, equal to their sum, to get the condition $g = 0$.

If the battery, E′, were well insulated the method might be found useful for testing the resistances of cables, while the bridge would retain its sensibility by the greater equality which might be thus maintained between the intensities, a, b, c, and d, than by the ordinary method.

Supposing, for instance,

A = 1,000 units
B = 10 „
D = 10,000 „
E = 1 cell (Daniell's)
E′ = 100 ditto in the same direction,

These inserted in their proper places in the formula

$$C = \frac{AD}{B} + \frac{E'}{E} \cdot \frac{A(B + D)}{B}$$

give

$$C = 101 \cdot 1 \text{ millims.}$$

about the resistance of five knots of Atlantic cable under atmospheric pressure, and a temperature of 75° Fah.

A thermo-electric current which was found to exist in using a bridge consisting of a long fine wire for the sides, A and B, a standard resistance at 32° Fah. in the side D, and a body of melted metal contained in a glass tube in the side C, suggested this little exercise.

THE ATLANTIC TELEGRAPH ENTERPRIZE.

By Amicus.

Newfoundland to Ireland, or from Ireland to Newfoundland, which you please; the question is whether, by virtue of the Yankees' being the "tallest nation," by a "tarnation slice," it is not entitled to precedence. True, Newfoundland is no part of the glorious model Republic—"the home of the brave," "the land of the free," &c.; but what then? it is on the same continent, is it not? and that is sufficient; and by-and-bye it will be absorbed, sucked in, or some such process, when that little bit of a job is finished down South, and Albion and Gaul have been "licked."

Eight years ago we telegraphists were just beginning to toddle, and like young venturesome, *ætat* eleven months and ten days, who thought he could strut across the room because he had succeeded in putting his right foot three inches in advance of his left for the first time, after repeated failures to maintain his centre of gravity, we likewise imagined, because we had connected Dover with Calais, and two or three other similar feats, we could also connect the two hemispheres, and while Jonathan was singing the nasal treble of "Hail Columbia" at New York, we could play seconds simultaneously by means of our submarine telegraph. But if our dream had come true at that time, it by no means follows that the performers of "Yankee Doodle" could have returned the compliment by taking up the bass to "God Save the Queen."

The best of the business was that we infantile waddlers had not only confidence ourselves in our own project, but everybody else had; and as a consequence, we raised a sufficiency of capital (as we thought) to accomplish it. Then didn't we strut and swell, and threaten "to put a girdle round the earth," and all sorts of fine things, with not so much as a thought upon the upsetting of our equilibrium. And we did it, too. It was a grand experiment, entitled to sympathy and support, and the public gave us largesse without stint, hoping, of course, to derive some benefit from the concern, and that they did not who deplores more than we? Never mind: seven years have passed since then, and although we have toppled over sundry times in the interval, we have determined, like Barnarby's parrot, never to say "die." Yes, some seven years ago our cable broke, in the first attempt to lay it, about 400 miles or so from the Green Island, and then we had to shut up for near upon a twelvemonth; but we had great confidence in ourselves all the time, and, better still, so had the public. So in '58 we solved the great problem scientifically and mechanically, and afforded Paddy an opportunity, if he had chosen to embrace it, of making over "Ould Oireland" *en masse* to the allegiance of Uncle Sam. Perish the quibbler who says he does not believe a message was sent through. Were you a shareholder, my man? If not, why then shut up; perhaps that is not polite, so good friend, oblige us with the proofs that we did not speak through the cable. Bah, one has no patience with a parcel of croakers. Why, man, there were three hundred messages sent through the short-lived cable, and that, every one will allow, was a good stroke of business for so short a time.

And we have gone on learning to walk all this time, and although we have ever and anon been feeble at the knees—nay, indeed, have had several falls and been severely bruised—we, nevertheless, managed to get on our pins again, and now do certainly feel stronger and better than we did. We certainly have not that overweening confidence in ourselves that we had before we made the essay at all, and it is but just to observe that the public have betrayed a still greater want of confidence in our abilities. This is not to be wondered at; over-confidence always suffers from a rebound, just as everything else does that is stretched beyond all reasonable limits.

Close upon the heels of our Atlantian prostration followed the collapse of the Red Sea cable, and two or three other

miserable matters, of which our poor person still retains the scars; but these are pretty well healed over now, and, indeed, we feel like a giant refreshed. (No, no; we are deaf at that ear. Somebody is whispering about the luckless shareholders of the old Atlantic telegraph having ugly wounds that still look red and inflamed; and about the national taxpayer—otherwise Mr. J. Bull—who is dreadfully sore about that Red Sea job, and considers his wounds bleed preciously, periodically. Clearly, however, we are not the right people for this worthy to come grunting to; we refer him to Downing-street. To the former we say, "Cheer up, you will be all right by-and-bye. Two hundred messages per day at 70s. each! look at that, and keep your own counsel.")

Let the Fates be praised, is not the considerable success of the Malta and Alexandria cable a proof that we have really begun to go; and reverting to the tardiness of public support now-a-days, we may be allowed to say that this line presents to them an instalment of the right sort of thing—an earnest of what we will do if they will only tip up. It is hard work certainly to struggle against wind and tide, but we mean to span the Atlantic in spite of everything comprised in cold shoulders, shrugged or otherwise. Yes, if we had waited for our old friend the public (many thanks for past favours), we should not have done this bit of business, which we hope will be quite completed by the eventful year 1866 (*vide* the modern prophets), until, perhaps—why no one knows when. But again let the Fates be praised; joint-stock undertakings are the levers wherewith we will revolutionize the world, and we mean to lace its old sides with telegraphic wicker-work, and to begin with, we shall demonstrate practically that telegraphic communication can be permanently and profitably laid and worked across the Atlantic. How many times we shall span it with separate cables is as yet undecided; but once having submerged one all right, we shall most assuredly go ahead, and attempt to realise that little bit of poetry respecting China, Australia, and various antipodean regions, which are to be electrically tacked to our tight little island in three years from date hereof. And as to intended operations in the Pacific, Arctic, Antarctic, and other oceans and seas, during the ensuing decennial period, why it would take one's breath away to make the catalogue; so forbear, little sprite, for the present, and let us confine ourselves to the matter in hand.

Yes, yes, joint-stock, that's the word now-a-days. Towards a renewed effort to attain this linking of the two hemispheres we have by this means, though not without tremendous private exertions, secured a goodly share of the required capital; and when we have got our cable laid, and in nice working order, with more work to do than we can get through, and all so profitable and pleasant, won't some sundry old stingers cry "peccavi;" but it will be of no use then, and they shall not revenge themselves on us by landing an opposition cable on our chartered territory. The amalgamation of two first-class firms into the Telegraph Construction and Maintenance Company have just afforded us the very means of doing the very thing we wanted to do.

This company consists of generous fellows, and they have stretched out the hand of fellowship to the directors of the Atlantic Telegraph Company in noble style. Here is the contract for making and laying, and all the rest, arranged as nicely as possible; and doubtless the work will be done to the mutual satisfaction of all parties, and to their profit also. And then all the world will profit by it as well, only think of that! There is a disinterestedness, too, about the terms of the contract and arrangements beyond all praise. Profit is contingent upon complete success. Who else would have manifested such magnanimity as herein immortalizes the T. C. and M. C.? And who else, pray, but the body whose initials are the foregoing would have taken up so goodly a portion of the unissued shares of the Atlantic Telegraph Company?

And now, be it known, we shall commence operations in 1865—that is, to lay the cable; it is in process of manufacture, as you very well know; the "core" is lengthening out, and the entire covering is also being applied; in all these matters, however, everybody is, or should be, well posted up. It will not be the editor's fault if you are not; and so we will pass on, please.

The old cable differed in many important respects from the one now in hand; this you also know, and these, therefore, are so many words thrown away; but they (not the verbiage) may be said to denote no inconsiderable advance in electrical science and telegraph cable manufacture.

There are plenty of people, no doubt, who will be very fast at criticising, ridiculing, and otherwise trying to bring both the cable and its promoters into contempt; but then, if this were not so, we know very well that it would afford a satisfactory proof that we were not living in the world—on this side of the millenium at least. We may surely say this much without having it attributed to us, that we affirm this cable to be beyond criticism, as the best that could possibly be devised. In fact, we are rather chary in our praises of it, not because it is not deserving of praise, but rather that we are exceedingly bashful, and would rather some one else did this part of the business; and we decidedly object to "damn it with faint praise," and so will merely say it is the result of careful inquiry, dearly bought experience, scientific deductions, and sundry other excellent motives which are always supposed to produce a good thing if properly worked together with a good leaven. At the risk of being thought egotistical, we will just remark that it is probably the best form of submarine telegraph at present available for submersion in very deep water, and for so long a stretch. It is a stupendous work, my masters, considering we telegraphists are yet in our non-age; but dear, dear, we shall arrive at puberty directly, and then manhood is close upon us.

To write on telegraphic matters is to repeat oneself *ad infinitum*, and sometimes *ad libitum*; this we particularly wish to avoid, and yet keep falling into it every dozen lines or so. Wonder if it will be considered repetition if we give the names of the scientific consulting committee? No, we will not; those who do not know ought to, and those who do do not want to be told. No doubt we shall be told as it is, that this body puts us in mind of an allopath, a homœopath, a herbalist, the founder of the College of Health, the village apothecary, and the doctoress who lives in the mud cottage down the lane that leads nowhere, all met together to decide as to the best way of treating young Harry Jones, who is down with the croup. A pretty way, indeed, to speak of eminent men, doctors and professors. What has become of the respect due to eminence and worth? For shame, ye carping critics! Would you have these worthy gentlemen leave the domain of tried experience to launch forth in a limitless, fathomless, untried ocean of theories, and that in so important a matter as an Atlantic telegraph? Now you just let these theories rest until we have time to attend to them.

These gentlemen agreed to differ, and that ought to satisfy everybody. What does it matter if any one of them, in a moment of excessive and indefensible candour, should impugn all personal responsibility as to having advised this or that? The constituents of this cable are precisely like all preceding ones—*i.e.*, copper (pray, what other conductor would you have?), gutta-percha, "ha! hum!" (pooh, what would you have, man?), hemp (an excellent material), and iron. A truce to your objections. The question is, whether the manufacture of a cable has not as much or more to do with its permanence and efficiency than the materials of which it is composed? being yet in our adolescence, however, we refrain from speaking too positively on this point, as also some others; we will treat you to a dogmatic discourse before long. We may just observe, however, that there are manifest improvements observed in the

manufacture, as it proceeds, that were never observed in any other cable.

The directors of the Atlantic Telegraph Company adopted this style of cable upon the recommendation of the report of the scientific consulting committee, who had a great many different forms to choose from, all of which were more or less subject to experiments in order to test their eligibility. So no more mouthing, please; this fact speaks for itself; and their being an heterogeneous conglomerate of discordant elements is all moonshine, besides being a slur upon the eminent conclave.

And then the contractors, to whom we have already referred, are well up in their business, have had a vast deal of experience, and, as we have seen, are by no means indisposed to share the risk; just the individuals are they to help us at this critical stage. Hurrah! then, and a fig for your prophecies. We will have something else to say next week, perhaps, on the detail of its component parts.

REPORT ON STANDARDS OF ELECTRICAL RESISTANCE.*

The Committee an Electrical Measurements, appointed in 1862, have not confined their attention to determining the best unit of electrical resistance, the point to which the duties of the committee of 1861 were nominally restricted, but have viewed this comparatively limited question as one part only of the much larger subject of general electrical measurement. The committee, after mature consideration, are of opinion that the system of so-called absolute electrical units, based on purely mechanical measurements, is not only the best system yet proposed, but is the only one consistent with our present knowledge both of the relations existing between the various electrical phenomena and of the connection between these and the fundamental measurements of time, space, and mass. The only hesitation felt by the committee was caused by doubts as to the degree of accuracy with which this admirable system could be or had been reduced to practice.

The measurement of voltaic currents, electromotive force, and quantity would offer little difficulty, provided only electrical resistance could be measured in absolute units; and for this purpose it would be sufficient that the resistance of a single standard conductor should be so determined, since copies of this standard could be multiplied at will with any desired precision; and from comparison with these copies, the absolute resistance of any circuit whatever could be obtained by methods requiring comparatively little skill and well known to all electricians. The practical adoption of the absolute system was felt, therefore, to depend on the accuracy with which the absolute resistance of some one standard conductor could be measured; and while doubts existed on this point, it was thought premature to make any extended experiments on the application of the absolute system to voltaic currents, electromotive force, or quantity. The committee are happy to report that these doubts have been dispelled by the success of the experiments made for the committee by Professor J. Clerk Maxwell, Mr. Balfour Stewart, and Mr. Fleeming Jenkin, according to the method devised by Professor W. Thomson. These experiments have been actively prosecuted at King's College for the last five months with continually increasing success, as, one by one, successive mechanical and electrical improvements have been introduced, and the various sources of error discovered and eliminated.

The sub-committee are confident that considerably greater accuracy can yet be obtained by the further removal of slight defects, the importance of which only became apparent when the main difficulties had been overcome. In order, therefore, to secure the best attainable result, and still further to test the accuracy and concordance of the experiments before taking any irrevocable step, the committee have decided not to issue standard coils at the present meeting; but the results already obtained leave no room for doubt that the absolute system may be adopted, and that the final standard of resistance may be constructed without any serious delay. Over-haste might eventually entail corrections as inconvenient as those which follow an arbitrary and unscientific choice of units; and the very experiments made by the sub-committee prove that the hesitation of many to adopt the absolute units as hitherto determined was well founded. It is certain that resistance-coils purporting to have been constructed from previous absolute determinations do not agree one with another within 7, 8, or even 12 per cent.

Before further alluding to the results obtained by the sub-committee, it is desirable that the experiments themselves should be understood; and to this end the committee have thought fit that a full explanation of the meaning of absolute measurement, and of the principles by which absolute electrical units are determined, should form part of the present report, especially as the only information on the subject now extant is scattered in detached papers by Weber, Thomson, Helmholtz, and others, requiring considerable labour to collect and understand. In order to make this account as clear as possible, it has been thought best to disregard entirely the chronological order of the discoveries and writings on which the absolute system is founded, and this has rendered it very difficult to refer to the original source of each statement or conclusion.

The word "absolute" in the present sense is used as opposed to the word "relative," and by no means implies that the measurement is accurately made, or that the unit employed is of perfect construction; in other words, it does not mean that the measurements or units are absolutely correct, but only that the measurement, instead of being a simple comparison with an arbitrary quantity of the same kind as that measured, is made by reference to certain fundamental units of another kind treated as postulates. An example will make this clearer. When the power exerted by an engine is expressed as equal to the power of so many horses, the measurement is not what is called absolute; it is simply the comparison of one power with another arbitrarily selected, without reference to units of space, mass, or time, although these ideas are necessarily involved in any idea of work. Nor would this measurement be at all more absolute if some particular horse could be found who was always in exactly the same condition and could do exactly the same quantity of work in an hour at all times. The foot-pound, on the other hand, is one derived unit of work, and the power of an engine when expressed in foot-pounds is measured in a kind of absolute measurement, *i.e.*, not by reference to another source of power, such as a horse or a man, but by reference to the units of weight and length simply—units which have been long in general use, and may be treated as fundamental. In this illustration, chosen for its simplicity, the unit of force is assumed as fundamental, and as equal to that exerted by gravitation on the unit mass; but this force is itself arbitrarily chosen, and is inconstant, depending on the latitude of the place of the experiment.

In true absolute measurement the unit of force is defined as the force capable of producing the unit velocity in the unit of mass when it has acted on it for the unit of time. Hence this force acting through the unit of space performs the absolute unit of work. In these two definitions, time, mass, and space are alone involved, and the units in which these are measured, *i.e.*, the second, gramme, and metre, will alone, in what follows, be considered as fundamental units. Still simpler examples of absolute and non-absolute measurements may be taken from the standards of capacity. The gallon is an arbitrary or non-absolute unit. The cubic foot and the litre or cubic decimetre are absolute units. In fine, the word absolute is intended to convey the idea that the natural connexion between one kind of magnitude and another has been attended to, and that all the units form part of a coherent system. It appears probable that the name of "derived units" would more readily convey the required idea than the word "absolute," or the name of mechanical units might have been adopted; but when a word has once been generally accepted, it is undesirable to introduce a new word to express the same idea. The object or use of the absolute system of units may be expressed by saying that it avoids useless coefficients in passing from one kind of measurement to another. Thus, in calculating the contents of a tank, if the dimensions are in feet, the cubic contents are given in cubic feet, without the introduction of any coefficient or divisor; but to obtain the contents in gallons, the divisor 6·25 is required. If the power of an engine is to be deduced from the pressure on the piston and its speed, it is given in foot-pounds or metre-kilogrammes per second by a simple multiplication; to obtain it in horse-power the coefficients 33,000 or 550 must be used. No doubt all the natural relations between the various magnitudes to be measured may be expressed and made use of, however arbitrary and incoherent the units may be. Nevertheless the introduction of the numerous factors then required in every calculation is a very serious annoyance, and moreover, where the

* This Report was prepared by a Committee appointed by the British Association, consisting of Professor Wheatstone, Professor Williamson, Mr. C. F. Varley, Professor Thomson, Mr. Balfour Stewart, Mr. C. W. Siemens, Dr. A. Matthiessen, Professor Maxwell, Professor Miller, Dr. Joule, Mr. Fleeming Jenkin, Dr. Esselbach, and Sir C. Bright.

relations between various kinds of measurement are not immediately apparent, the use of the coherent or absolute system will lead much more rapidly to a general knowledge of these relations than the mere publication of formulæ.

The absolute system is, however, not only the best practical system, but it is the only rational system. Every one will readily perceive the absurdity of attempting to teach geometry with a unit of capacity so defined that the contents of a cube should be 6¼ times the arithmetical cube of one side, or with a unit of surface of such dimensions that the surface of a rectangle would be equal to 0·000023 times the product of its sides; but geometry so taught would not be one whit more absurd than the science of electricity would become unless the absolute system of units were adopted.

In determining the unit of electrical resistance and the other electrical units, we must simply follow the natural relation existing between the various electrical quantities, and between these and the fundamental units of time, mass, and space. The electrical phenomena susceptible of measurement are four in number—current, electromotive force, resistance, and quantity. The definitions of these need not now be given. Their relations one to another are extremely simple, and may be expressed by two equations.

First, by Ohm's law, experimentally determined, we have the equation

$$C = \frac{E}{R}, \qquad (1)$$

where C = current, E = electromotive force, and R = resistance. From this formula it follows that the unit electromotive force must produce the unit current in a circuit of unit resistance; for if units were chosen bearing any other relation to each other, C would be equal to $x\frac{E}{R}$, where x would be a useless and absurd factor, complicating all calculation, and confusing the very simple conception of the relation established by Ohm's law.

Secondly, it has been experimentally proved by Dr. Faraday that the statical quantity of electricity conveyed by any given current is simply proportional to the strength of the current, whether electromagnetically or electrochemically measured, and to the time during which it flows; hence, in mathematical language, we have the equation

$$Q = Ct, \qquad (2)$$

where t = time, and Q = quantity. From this equation it follows that the unit of quantity must be the quantity conveyed by the unit current in the unit of time; otherwise we should have $Q = yCt$, where y would be a second useless and absurd coefficient. From equations (1) and (2) it follows that only two of the electrical units could be arbitrarily chosen, even if the natural relation between electrical and mechanical measurements were disregarded. Thus if the electromotive force of a Daniell's cell were taken as the unit of electromotive force, and the resistance of a metre of mercury of one millimetre section at 0° were taken as the unit of resistance, it would follow from equations (1) and (2) that the unit of current must be that which would be produced by the Daniell's cell in a circuit of the above resistance, and the unit of quantity would be the quantity conveyed by that current in a second of time. Such a system would be coherent; and if all mechanical, chemical, and thermal effects produced by electricity could be neglected, such a system might perhaps be called absolute. But all our knowledge of electricity is derived from the mechanical, chemical, and thermal effects which it produces, and these effects cannot be ignored in a true absolute system. Chemical and thermal effects are, however, now all measured by reference to the mechanical unit of work; and therefore, in forming a coherent electrical system, the chemical and thermal effects may be neglected, and it is only necessary to attend to the connexion between electrical magnitudes and the mechanical units. What, then, are the mechanical effects observed in connexion with electricity? First, it has been proved that whenever a current flows through any circuit it performs work, or produces heat or chemical action equivalent to work. This work or its equivalent was experimentally proved by Dr. Joule to be directly proportional to the square of the current, to the time during which it acts, and to the resistance of the circuit; and it depends on these magnitudes only. In mathematical language this is expressed by the equation

$$W = C^2 Rt, \qquad (3),$$

where W = the work equivalent to all the effects produced in the circuit, and the other letters retain their previous signification. This is the third fundamental equation affecting the four electrical quantities, and represents the most important connexion between them and the mechanical units. From equation (3) it follows (unless another absurd coefficient be introduced) that the unit current flowing for a unit of time through a circuit of unit resistance will perform a unit of work or its equivalent. If every relation existing between electrical and mechanical measurements were expressed by the three fundamental equations now given, they would still leave the series of units undefined, and one unit might be arbitrarily chosen from which the three other units would be deduced by the three equations; but these three equations by no means exhaust the natural relations between mechanical and electrical measurements. For instance, it is observed that two equal and similar quantities of electricity collected in two points repel one another with a force (F) directly proportional to the quantity (Q), and inversely to the square of the distance (d) between the points. This gives the equation

$$F = \frac{Q}{d^2}; \qquad (4)$$

from which it would follow that the unit quantity should be that which at a unit distance repels a similar and equal quantity with unit force. The four equations now given are sufficient to measure all electrical phenomena by reference to time, mass, and space only, or, in other words, to determine the four electrical units by reference to mechanical units. Equation (4) at once determines the unit of quantity, which, by equation (2), determines the unit current; the unit of resistance is then determined by equation (3), and the unit electromotive force by equation (1). Here, then, is one absolute or coherent system, starting from an effect produced by electricity when at rest. The units based on these four equations are precisely those called by Weber electrostatical units, although it may be observed that he chose those units without reference to what is here called the third fundamental equation, or, in other words, without reference to the idea of work, introduced into the system by Thomson and Helmholtz.

The four equations are sufficient to determine the four units, and into this system no new relation can be introduced. The first three equations may, however, be retained, and a distinct absolute system established by substituting some other relation between electrical and mechanical magnitudes than is expressed in equation (4); and, indeed, the electrostatical system just defined is not that which will be found most generally useful. It is based on a statical phenomenon, whereas at present the chief applications of electricity are dynamic, depending on electricity in motion, or on voltaic currents with their accompanying electromagnetic effects. Now the force exerted on the pole of a magnet by a current in its neighbourhood is a purely mechanical phenomenon. This force (f) is proportional to the magnetic strength (m) of the pole of the magnet, and to the strength of the current (C); and if the conductor be at all points equidistant from the pole, or, in other words, be bent in a circle of the radius k round the pole, the force is proportional to the length of the conductor (L): it is also inversely proportional to the square of the distance (k) of the pole from the conductor, and is affected by no other circumstances than those named. Hence we have

$$f = \frac{CLm}{k^2}. \qquad (5)$$

From this equation it follows that the unit length of the unit current must produce the unit force on a pole at the unit distance. If the equations (1), (2), (3), and (5) are adopted as fundamental, they give a distinct absolute system of units, called by Weber the electromagnetic units. Equations (4) and (5) are incompatible one with another, if equation (2) be considered fundamental; but the electromagnetic units have a constant and natural relation to the electrostatic units. It will be seen that in the fundamental equation (5) of the electromagnetic system, besides the measurements of time, space, and mass, alone entering into the other equations, a fourth measurement (m) of a magnetic pole is required; but this measurement is in itself made in terms of the mechanical units, for the unit pole is simply that which repels another equal pole at unit distance with unit force. Thus in the electromagnetic, as in the electrostatic system, all measurements are ultimately referred to the fundamental units of time, space, and mass. The electromagnetic units are found much the more convenient when dealing, as we have now chiefly occasion to do, with electromagnetic phenomena.

The relations of the electromagnetic units one to another and to the mechanical units may be summed up as follows:—The unit current conveys a unit quantity of electricity through the circuit in a unit of time. The unit current in a conductor of unit resistance produces an effect equivalent to the unit of work in the unit of time. The unit current will be produced in a circuit of unit resistance by the unit electromotive force. The unit current flowing through a conductor of unit length will exert the unit force on a unit pole at a unit distance. (In the electrostatic system all the above propositions hold good except the last, for which the following must be substituted:—the unit quantity of electricity

will repel a similar quantity at the unit distance with a unit force.)

It remains to be explained how electrical measurements can be practically made in electromagnetic units. Of all the magnitudes, currents are the most easily measured, provided the horizontal force (H) of the earth's magnetism be known. Let a length (L) of wire be wound so as to form a circular coil of small section as compared with its radius (k).

Let a short magnet be hung in the centre of the coil placed in the magnetic meridian, as in the ordinary tangent galvanometer, and let the deflection produced by the current C be called d, then it is easily* proved from the fundamental equation (5) that

$$C = \frac{Hk^2}{L} \tan d. \qquad (6)$$

Thus, where the value of H is known, a tangent galvanometer only is required to determine the magnitude of a current in electromagnetic absolute measurement, although neither the resistance of the circuit nor the electromotive force producing the current may be known. The measurement of quantity can be obtained from that of a current by a make-and-break apparatus, or "Wippe," in a well-known manner, or by measuring the swing of a galvanometer needle when a single instantaneous discharge is allowed to pass through it. If, therefore, we could measure resistance in absolute measure, the whole system of practical absolute measurement would be complete, since, when the current and resistance are known, equation (1) (Ohm's law) directly gives the electromotive force producing the current. The object of the experiments of the sub-committee (made at King's College by the kind permission of the principal) was therefore to determine the resistance of a certain piece of wire in the absolute system, in order from this one careful determination to construct the material representative of the absolute unit with which all other resistances would be compared by well-known methods.

There are several means by which the absolute resistance of a wire can be measured. Starting from equation (3), Professor Thomson, in 1851, determined the absolute resistance of a wire by means of Dr. Joule's experimental measurement of the heat developed in the wire by a current;† and by this method he obtained a result which agrees within about 5 per cent. with our latest experiments. This method is the simplest of all, so far as the mental conception is concerned, and is probably susceptible of very considerable accuracy.

Indirect methods depending on the electromotive force induced in a wire moving across a magnetic field have, however, now been more accurately applied; but, before describing these methods, it will be necessary to point out the connexion between the electromotive force induced in the above manner and the fundamental equations adopted for the absolute system. The exact sense in which the terms are employed is defined in the accompanying footnote, along with simple corollaries from those definitions.‡

A current (C) in a straight conductor of length (L) crossing the lines of force of a magnetic field of the intensity (S) at right angles will experience the same force (f) as if all the points of the conductor were at the unit distance from a pole of the strength (S). The force in this case exerted on the magnet is, by equation (5), equal to SLC, and, conversely, an equal force is exerted by the magnet on the current. Hence we have equation (7), expressing the value of the force (f) exerted on a current crossing a magnetic field at right angles,

$$f = SLC \qquad (7)$$

Let us imagine this straight conductor to have its two ends resting on two conducting rails of large section in connexion with the earth, and let the whole sensible resistance (R) of the circuit thus formed be constant for all positions of the conductor. Let us further imagine the rails so placed that when the conductor slips along them it moves perpendicularly to the magnetic lines of force and to its own length. By experiment we know that when the conductor is moved along the rails cutting these lines of force, a current will be developed in the circuit, and that the action of the magnetic force on this current will cause a resistance (f) to the motion (due to electromagnetic causes only); and, by equation (7), we find that this resistance $f = SLC$.

Let the motion be uniform, and its velocity be called V; and let the work done in the unit of time in overcoming the resistance to motion due to electromagnetic causes be called W; then $W = VSLC$. But this force produces no other effect than the current, and the work done by the current must therefore be $= W$, or equivalent to that done in moving the conductor against the force f, but, by equation (3), $W = C^2R$, and hence

$$R = \frac{VSL}{C} \qquad (8)$$

(To be continued.)

* The resultant electromagnetic force (f) exerted at the centre of the coil by a current (C) will, by equation (5), be $f = \frac{CL}{k^2}$, and the short magnet hung in the centre will experience a couple acting in a direction perpendicular to the plane of the coil equal to $\frac{CLml}{k^2}$, where ml = the product of the strength of one of the poles into the length of the magnet, or, in other words, its magnetic moment. The strength of the couple acting perpendicularly to the axis of the magnet, when it has deflected to an angle d under the influence of the current, will be $\cos d \frac{CLml}{k^2}$, at the same time the equal and opposite couple exerted on the magnet by the earth's magnetism will be $\sin d\, Hml$, hence

$$C = \frac{Hk^2}{L} \times \frac{\sin d}{\cos d} = \frac{Hk^2}{L} \tan d.$$

† Phil. Mag. vol. ii. Ser. 4, 1851, p. 551.

‡ *Definition* 1.—A magnetic field is any space in the neighbourhood of a magnet.

Definition 2.—The unit magnetic pole is that which, at a unit distance from a similar pole, is repelled with unit force.

Definition 3.—The intensity of a magnetic field at any point is equal to the force which the unit pole would experience at that point.

Corollary 1.—A pole of given strength (S) will produce a magnetic field which (if uninfluenced by other magnetic forces) will at the unit distance from the pole be of the intensity S, *i.e.*, numerically equal to the strength of the pole; for, at that distance, the force exerted on a unit pole would, by def. 2, be equal to S, and hence, by def. 3, the intensity of the magnetic field at that point would be equal to S.

Definition 4.—The direction of the force in the field is the direction in which any pole is urged by the magnetism of the field; this is the direction which a short-balanced, freely suspended magnet would assume.

Remark.—The properties of a magnetic field, as shown by Dr. Faraday, may be conveniently and accurately conceived as represented by *lines of force* (each line representing a force of constant intensity). The direction of the lines will indicate the direction of the force at all points; and the number of lines which pass through the unit area of cross section will represent the magnetic intensity of the field resolved perpendicularly to that area.

Definition 5.—A uniform magnetic field is one in which the intensity is equal throughout, and hence, as demonstrated by Professor W. Thomson, the lines of force parallel.

Example.—The earth is a great magnet. The instrument-room, where experiments are tried, is a magnetic field. The dipping-needle is an instrument by which the direction of the lines of force is found. The intensity of the field is found by a method described in the "Admiralty Manual," 3rd edit., article "Terrestrial Magnetism." The number of lines of force passing through the unit of area perpendicularly to the dipping-needle in the room must be conceived as proportional to this intensity, and the direction to correspond with that of the dipping-needle. The magnitude and direction of the earth's force at a point are generally expressed by resolving it into two components, one horizontal and the other vertical. The mean horizontal component in England for 1862 was at Kew = 3·8154 British units, or 1·7592 metrical; *i.e.*, a unit pole weighing one gramme, and free to move in a horizontal plane, would, under the action of the earth's horizontal force, acquire, at the end of a second, a velocity equal to 1·7592 metres per second.

APPARATUS FOR MEASURING THE VELOCITY OF PROJECTILES.

The electro-ballistic apparatus, now in use at Woolwich and Shoeburyness, was invented by Major Navez, of the Belgian Artillery, for measuring a very small space of time—such, for instance, as a cannon-ball would take in passing over a few yards. Before we [*Illustrated London News*] proceed to explain this interesting machine, it will be necessary to remind our readers that an electric current has the property of magnetizing soft iron, and also to mention the peculiar principle of the pendulum. This is that the same pendulum will always, within certain limits, perform unequal vibrations in equal times—that is to say, that a "seconds" pendulum will always take "a second" to make one oscillation, whether it be raised from the perpendicular 20° or 5°. Consequently, supposing a seconds pendulum to be selected, we can take the arc it describes in one vibration, and, by dividing this arc into a scale of parts, we can arrest the pendulum as it falls; and the distance it has fallen, measured into the whole length of the arc, will give us the fraction of a second in which the fall took place. We see, then, with what extreme minuteness we can measure time by stopping the seconds pendulum before it has fallen the thousandth part of the arc in which

it would vibrate. The electro-ballistic apparatus is used for determining the velocity of a projectile, or the rate at which a shot proceeds after it leaves the muzzle of a gun. The instrument consists of three separate parts, one of which is a principal and the others accessories. The chief part consists of a graduated arc, on which a pendulum is so adjusted that it can be arrested at any period of its oscillation, and thus denote the time it has taken to fall. The pendulum, before an observation, is held suspended at the left extremity of the arc, by means of a piece of soft iron in the centre of the bob, which is magnetized by an electric current through an electro-magnet at the point of support. Connected with this magnet are two insulated wires, which pass away for two or three hundred yards, and terminate by the ends being wound across an upright screen, thirty yards in front of the gun, where the ends are joined, so that the electric circuit is complete. Another instrument is employed called the conjunctor, and performs the following office. At the top of it an electro-magnet, which is connected by wires with a second screen, 120 feet in front of the first—*i. e.*, 150 feet from the gun. These wires are insulated with gutta-percha, &c., so that they may be either buried in the ground or hung on posts. The electro-magnet in the conjunctor retains a small weight suspended over a cup of mercury. This has a steel blade above it, with a pin so arranged that if the weight falls it presses it into the mercury. The pendulum has an index or duplicate pendulum in rear, which is so attached to it by a light spring, that it will fall and oscillate with the pendulum proper. Behind the machine is a large electro-magnet, which has power to attract this index when magnetized.

Upon the gun being fired, the projectile cuts the wires of the first screen, and thus demagnetizes the electro-magnet which holds up the pendulum. This latter commences to fall, and the index-needle with it, along the graduated arc. When the second screen is cut through by the shot, the electro-magnet at the top of the conjunctor is demagnetized, and the weight falls into the mercury, pressing down the steel blade, and completes another electric circuit, which magnetizes the large magnet in rear of the pendulum, and clamps the index-needle against the scale on the arc. The operator then reads off the scale the distance which is marked by the index, and the time thus measured is that which the shot took to pass through the screens, minus the time necessary for the weight to fall in the conjunctor, and which the operator, before commencing, finds by means of the disjunctor. A table has been prepared which shows the time for the pendulum to fall down any arc from 0° to 150°, and only needs to be referred to for any arc through which it falls when used as above. The time thus given has only to be divided into the distance between the screens, and the result will be the velocity of the projectile. By this contrivance a skilful operator is able to measure pretty accurately to the three-thousandth part of a second. Such wonderful precision renders this instrument most valuable for artillery scientific purposes, and many most important problems have been solved by its use.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XVI.

A.D. 1841, January 11.—No. 8783.—Barwise, John, and Bain, Alexander.—"Improvements in the application of moving power to clocks and timepieces," consisting of:—

"A method of applying the pendulum of a regulating clock or timekeeper for making or breaking alternately the electric connection between the source of electricity and the electro-magnetic clocks and timepieces." A "regulating clock" conveys an electric current, and cuts it off periodically, by means of equidistant metal studs let into an ivory ring, over which a metal spring on the escape-wheel axis moves; the spring is connected with one battery pole, and completes communication with various wires leading to electro-magnetic clocks, each stud having a wire. Sixty studs giving motion to sixty clocks, are shown, so that each clock is moved once every minute if the pendulum beats seconds. A wire leads from each stud to one end of the coil of an electro-magnet in a clock or set of clocks, consequently every beat of the pendulum of the regulating clock will put in motion an electro-magnetic clock; the return wire to the battery is continuous, and is connected with the remaining terminal of the coil of the electro-magnet in each clock. The electro-magnetic clock consists of a train of wheels, the escape-wheel of which is moved one tooth by means of a spring and "catch-spring," fastened at its bottom angle, connected with a soft iron armature, every time an electro-magnet is discharged.

A "method of working simultaneously a number of clocks." The pendulum of the regulating clock completes the circuit every time a spring which it carries, connected with one battery pole, passes over a "metal conductor" connected with the other battery pole. This plan requires more battery power than the former.

A means of winding up the going and striking train and setting the hands of a clock once every hour. Sixty electro-magnetic clocks are connected with the positive and negative wire from the battery and regulating clock, but each clock only forms a closed circuit once every hour, when a metal stud inlaid in a disc comes into contact with a spring. An electric current is made to traverse once every minute by the regulating clock, which acts on that particular electro-magnetic clock in which the circuit is unbroken. In the electro-magnetic clock, a horizontal sliding bar is free to move backwards and forwards, by the attraction to the electro-magnet of a keeper fixed to the bar, and the reactive pressure of "a gun-lock spring;" this bar carries spring catches, working into the teeth of ratchet wheels on the main-spring axis of the going and striking trains; thus partly winding up the main-springs. Attached to the sliding-bar is an arm with prongs, which take hold of a projecting pin on the disc fixed to the minute-hand spindle, and, by the sliding motion, set it to its proper time; when the electro-magnet is discharged, the pin is out of the way of the prongs.

A method of bringing the minute hand of an ordinary clock "(provided it deviate not more than a minute from the time of the regulating clock) to exact time with the regulating clock," by actuating an electro-magnet whose keeper moves two clips working on pivots attached to the front plate of the clock; on the magnetism ceasing, the clips are separated by a spring forcing the keeper from the magnet. The circuit is completed at the proper time by a piece of metal inlaid in an ivory disc, over which a spring (in the circuit), fixed to the minute hand axis, traverses. By varying the position of the spring in each clock a number of clocks may be set in succession.

"A mode of supplying the voltaic battery with sulphate of copper or other suitable materials," by causing two rings, between which cups are free to turn, to revolve and bring levers on their axes into contact with a spring fixed on the battery cell, thus overturning the cups at certain times.

A number of wires for transmitting the above currents twisted together like a rope, "or the positive and negative wires are twisted with hemp or other fibrous rope."

A timepiece worked solely by electro-magnetism. The electro-magnet acts on a keeper fixed on to the pendulum, which has a "catch-spring" that works the "escapement wheel" connected with ordinary clockwork. A spring on a "sliding rod," worked by the pendulum by means of shoulders, comes periodically into contact with a "stud," and completes the circuit at suitable times.

Making a balance timekeeper transmit the electric current to other clocks, as in the first improvement, by a stud on the seconds wheel, which passes over an inlaid ivory ring.

"The application of an electric current to the striking of a clock." "The gathering palette wheel" "of the striking train, which makes one revolution for each blow of the hammer on the bell," has a projecting spring, which, striking against a stud, completes the electric circuit, and causes the hammer to strike the bell; for that purpose the hammer rod carries an armature which is attracted to the electro-magnet whenever the circuit is completed.

"A method of giving motion to a number of clocks." "By this method five" [three?] "long conducting wires are required." On a spindle of a pendulum or balance clock, a spring is fixed, connected with the positive battery wire, which moves uniformly over a fixed non-conducting disc, having two metallic half circles, with which two long conducting wires are respectively in contact; the current is thus transferred to the wires alternately. Another long conducting wire returns the electric current. Each electro-magnetic clock has two electro-magnets, each respectively connected with each positive wire; a soft iron frame is suspended between their poles, containing "catch springs" that work the clockwork. As soon as the frame of the first clock is attracted to its magnet it completes the circuit for the next clock, and so on; thus completing the circuit to as many clocks, in succession, as the time the regular spring is in contact with one half-circle will allow.

When the regulator spring moves over the other half circle it puts into action the second set of magnets.

A combination in which a regular clock, marking Greenwich time, enables uniform time to be shown throughout the country. A circuit to a distant station battery and regulator is actuated by the central regulator, that actuates a second, and so on. The clocks in the neighbourhood of each station may be worked as in the first improvement.

A.D. 1841, January 14.—No. 8793.—Jones, Alexander.—"Improvements in the manufacture of copper tubes and vessels." "Manufacturing tubes and vessels of copper deposited or thrown down in the form and of the substance of the tube or vessel required to be manufactured, by the action of voltaic electricity." "A solid or other mould, of the diameter and form of the required tube," is made of "wood, clay, earthenware, plaster of Paris, wax, or other non-conducting substance," "or the mould may be of lead or other metal fusible at a less degree of heat than the copper of which the tube is to be formed." A non-conducting mould is made conducting by the application of nitrate of silver solution, the metal being afterwards reduced by immersion in a solution of proto-sulphate of iron, or by phosphorus, either in solution or in vapour; or plumbago, metallic leaf or foil, or bronze powder, may be used. The mould is then placed in a vessel containing a solution of sulphate or nitrate of copper, connected to the "positive plate" of a suitable galvanic battery, and "surrounded by a cylinder of copper of a larger interior diameter than the required tube," which cylinder is connected with the "negative plate" of the battery; instead of a cylinder, clippings, turnings, or other refuse of copper," "placed in a frame of wicker work," may be connected to the "negative plate" of the battery. When the deposit of copper, thus caused, is of the required thickness, it may be removed from the mould either by mechanical force or by heat. It may be necessary to form vessels in separate portions, which may be done by galvanic electricity as follows:—Every part, except the edges to be joined and a small portion on each side, is coated with a "resinous varnish;" the parts are brought together as they are required to be fixed, the whole is immersed in the copper solution, and connected with the battery as aforesaid, with a copper plate in connection with the battery surrounding it. A single cell apparatus, with diaphragm and constant supply of sulphate of copper, may be used instead of a separate galvanic battery.

A.D. 1841, January 23.—No. 8809.—Baggs, Isham.—The title of this invention is, "Improvements in printing." The invention relates:—1st. To the application of "the chemical powers of electricity," "however obtained," "to the purpose of printing in one or more colours." When "quantity" electricity is used, a design is prepared for printing by forming the parts of various metals or metallic alloys, this design is placed upon paper "slightly moistened" with a suitable chemical solution, and the paper is placed upon "the negative pole of an active battery;" on the connection of the metallic design "with the positive wire," electro-chemical affinities operate, and a coloured impression of the design is produced. When "electricity of high tension and small quantity" is used, a design is "formed upon a glass plate by cementing upon its surface a number of small pieces of very fine platinum," or other metallic "wire, in consecutive order, so as to form a series; it is then to be laid upon a sheet of paper moistened with any appropriate solution," "and submitted to the action of a spark or current." 2nd. "To a mode of employing tests in printing," by using paper moistened with solutions of various re-agents, when more colours are required than one re-agent can produce.

A.D. 1841, March 8.—No. 8865.—Spencer, Thomas.—This invention is entitled, "An improvement or improvements in the manufacture of picture and other frames and cornices, applicable also to other useful and decorative purposes," and it relates to:—1st. The "application of voltaic electricity" to the above purposes, by taking a mould from a model of the required design, and a copper electrotype from that mould. The mould may be either cast in any suitable substance or electrotyped. If the mould is not metallic it must have its surface made conductable, preferably, by giving it a "coating of thin varnish;" when nearly dry, "bronze powder" is applied until the whole surface is "rendered metallic." The electric apparatus may be a single cell, but preference is given to the battery process. When the deposit is thick enough, the copper frame may be removed "by a slight application of heat." The back of the frame may be filled with solder, and a "rabbit" fastened entirely round it for the picture and glass to be fitted into. The frame is then ready to be gilt, silvered, or covered with platinum. 2nd. The "application of voltaic electricity to the manufacture of moulds" for casting "composition" and "papier mâché" ornaments, "also for casting glass, earthenware, and china." An exact model is fastened to a plate of polished metal or glass by varnish. The model and plate (if non-conductable) must then be "metalized" and electrotyped in copper, the electrotype may then be removed and tinned on the back, or it may be electrotinned before its removal from the model. Lead, or other suitable substance, is then poured on the back of the mould to make it "level." Moulds for casting in glass may be made by metallizing a cut and polished article of glass and depositing on it. 3rd. The "application of voltaic electricity for the purpose of making patterns or moulds for ironfounders in copper." For this purpose a cast is taken from an original pattern—if non-conductable, metallized—and electrotyped in copper. To obtain uniform thickness, the surface to be deposited on should be placed horizontal, opposite to the dissolving plate which lies at the bottom of the depositing vessel. 4th. The "use of bromine and iodine combined with gold, in conjunction with voltaic electricity, for the purposes above enumerated." Gold is dissolved in bromine, either by adding gold leaf, or by the help of alcohol, acetic acid, and sulphuric acid, in certain proportions; the gold plate being attached to the "platinum end of a galvanic battery." This solution is used slightly diluted. When a thick deposit of gold is required, "an ammoniacal salt" is added to the solution of gold; an alkaline carbonate is added, when the metal to be gilt reduces the gold by immersion. The solution of iodide of gold in "acetate or muriate of ammonia," or in "prussiate of potassa," may be used instead of the bromine solution. "A device or embossment" may be formed in gold by using "a reverse of the design" electrotyped by the above solution. 5th. "The use of bromine and iodine combined with silver, and in conjunction with voltaic electricity," for the purposes above enumerated. For an electro-depositing solution, silver dissolved in acetate of ammonia, proceeding as with gold, or in bromine and alcohol by electricity; the solution is suffered to rest "until a yellowish white precipitate takes place," which is dissolved in acetate of ammonia by boiling. Other ammoniacal salts or "prussiate of potassa" may be used; or a solution may be formed by dissolving an iodide of silver in "prussiate of potassa," or any of the ammoniacal salts. 6th. Methods of electro-coating metallic surfaces with platinum. To prepare the solution, the "platino-bichloride of ammonia" is added to weak hydrochloric acid, and boiled, or platinum is dissolved by electricity in "muriate of ammonia;" or when bromine is used, spongy platinum is dissolved in a mixture of alcohol and bromine, and dilute sulphuric acid added; or the "platino-bichloride of ammonia" may be combined with the alcoholic solution of bromine. Lead may be coated by either of these solutions, and used as the negative plate of a galvanic battery. 7th. "Covering metallic surfaces with tin." The solution used for electro-tinning is of "acetate of ammonia or muriate of that salt or suphat" [sulphate?] "of soda; this is used in the ordinary manner." 8th. Methods of cleaning the surfaces of iron that are to be coated with copper, and of electro-coating those surfaces. The iron is attached to the "platinum end of a voltaic battery," and immersed opposite to another iron surface, connected with the "zinc end," in a solution of sulphate of soda, or malleable iron may be cleaned by immersion in a solution of sulphate of zinc containing a very small quantity of any salt of copper. The iron is then to be electro-coated with copper by proper contact with a suitable galvanic battery, and immersion in a solution of "the acetate, sulphate, nitrate, or the ammonia acetate" [ammonia-acetate?] "of copper." 9th. A "method of producing embossed or enriched surfaces" on picture frames, &c., by the use of embossed calico, &c. 10th. The "application of caoutchouc" to improve "the texture of composition used to cast ornaments" for picture frames, &c.

A.D. 1841, March 29.—No. 8905.—Parkes, Alexander.—"Certain improvements in the production of works of art in metal by electric deposition." These relate "to the manufacture of works of art in silver and of gold, by causing these metals to be deposited by electric agency in or on suitable moulds or models," "in place of producing such articles by casting, or by pressure, or hammering, or stamping in dies or shapes." Under the heads of "internal" and "external" moulds, the specification and drawings describe various methods of making moulds from other moulds, models, or patterns, to electro-deposit gold or silver in or on, which moulds may be removed by heat or otherwise; a method of making the said moulds by electro-deposition; various means of making the moulds, such as employing wax, stearine, and fusible or other

metal, so that they may be removed from the deposit "by heat or solution;" making the moulds or models up of parts, so that they may serve for many copies of the deposited article, or to enable the moulds to be "highly finished," or "internal" moulds to be obtained in one piece from "external" patterns in parts; and a "mode of strengthening articles of gold and silver produced in or on moulds by electric depositions, by introducing a baser metal within them," either electro-deposited or by fusion. In an "internal" mould the face or pattern of the article is against the mould, and in an "external" mould the face is away from the mould, the mould merely imparting form by the equality of the thickness of the deposit. Details respecting solutions, fusible metal, coating and preparing non-metallic moulds, removal of moulds, battery, &c., are given.

A.D. 1841, April 27.—No. 8937.—Petrie, William.—"The application of the deflective action which exists between electric currents and magnets for "the purpose of obtaining a moving power." The specification and drawings describe and show an electro-motive engine in which "two rectangular helices" (one including the other) cross each other at right angles, and "are fixed in a suitable framework;" an axis, in proper bearings, passes freely through one side of the helices, and "on that part of the axis within the helices are placed magnets with similar poles adjacent;" these may either be electro-magnets or permanent magnets. A "current-changer" attached to the axis enables the electric current to traverse one helix, then the other, then again the first helix in the opposite direction, then the second helix in the opposite direction, and so on; thus producing a constant tendency of the magnets to deflect in the same direction, from each of the coils respectively, and giving, therefore, a rotary motion to the magnet's axis. A description of a "spark-preventer" is also given, in which a "bridge" on the "current-changer," "attached to a spring," is made to complete a "short circuit" between the poles of the battery during the changing of the current from one helix to the other, thus avoiding the disruptive discharge; two "bridges" are necessary, one for each helix. Another "spark-preventer" is also described, in which an additional "inlaid strip" on the current-changer," connected with one pole of the battery, is brought into connection with the other pole by one of the conductors proceeding to the helices, during the change of current. Remarks are made respecting the contruction and working of the engine, and the proportion of magnets and helices to battery power is minutely given.

A.D. 1841, May 14.—No. 8958.—Pinkus, Henry.—"An improved method or methods of applying electrical currents or electricity, either frictional, atmospheric, voltaic, or electro-magnetic." This invention relates to:—

The propulsion of "vessels at sea." Galvanic batteries are arranged on the external and internal sides of the ship, insulated from the vessel and from the sea by "a surface of pitched and resend felt," also "auxiliary" troughs are used. "The electro-magnetic engine of contact" (See No. 8644) by this means gives motion to the paddle wheels. To supply and circulate the sea water or other solution through the battery cells, and to assist in propelling the vessel, engines are erected in the ship, with "piston cylinders arranged with clack valves as blast cylinders for the compression or rarification of air, or arranged for forcing other fluids or water," worked by means of levers, connected to shafts proceeding through stuffing boxes to the outside of the vessel, the levers having floats, which move up and down according to the combined motions of the sea and the vessel. This "supply engine" compresses the air into reservoirs, and thus works an "auxiliary" engine connected to the paddle shaft; by means of pumps in connection with the tanks it also causes circulation through the battery cells. The "supply engine" may also have the bottoms of its cylinders open to the sea; its pistons will then be moved up and down at each motion of the vessel over the waves.

The application of the above electro-magnetic engine to canal propulsion. A "locomotive impelling engine" is mounted on a "suspension rail," and has toothed spur gearing working into a rack on the side of the rail, also horizontal guide wheels running on side rails; this engine is moved, either "by the electro-magnetic engine on the locomotive," or from the vessel by a cord passing round suitable pulleys; in the latter case, "a distending rod," capable of adjustment by nuts, and right and left handed screws, joins the centres of the pulleys; "the metallic circuits must be formed" as described in No. 8644.

Sealing and unsealing the "pneumatic valve," described in No. 8644. "Metallic circuits" are connected "with the valve mains, and so render" "soft iron bars," "magnets to hold down the flexible valve," by means of soft iron attached to its lips.

A.D. 1841, June 12.—No. 8987.—Palmer, Edward.—"Improvements in producing printing surfaces and printing china, pottery ware, music, maps, and portraits." These relate:—1st. To a mode of drawing and painting on a conducting surface, or on a surface afterwards made conducting, so that metallic plates, with sunken surfaces, can be obtained from them by the electrotype process, from which prints may be taken as from copper or steel plates. The drawing is made on a "whitened" plate with a dark composition (which is described, and the "handling" of it elucidated), the plate is then made conducting with plumbago (for instance), and electrotyped. 2nd. To a mode of drawing on the above-mentioned surfaces, so that metallic plates with raised surfaces, as in wood blocks, may be obtained for printing. The drawing is made on a "darkened" plate with a white composition (which is described, and the "handling" of it elucidated), the surface is then made conducting, and electrotyped. A method of "lowering the light parts" is given, which consists in pressing the original plate between millboard, thickened and cut out in appropriate places by a method described.

CHANGING IRON TO STEEL BY CARBONIC OXIDE.

M. Frederic Marguerite has recently presented a paper on this subject to the Academy of Sciences, Paris, from which *Le Genie Industriel* extracts the following:—

"The idea of carburation by a gas is due to Clonet, who thought that iron has such an affinity for carbon that at a very high temperature it would remove it even from oxygen. He relied for this opinion on the fact that having heated iron divided into small pieces with a mixture of carbonate of lime and clay, he obtained steel. He concluded that the carbonic acid of the carbonate of lime was decomposed, yielding its carbon to the iron.

"But Mushet, repeating the experiment of Clonet, operated with lime deprived of carbonic acid, or simply with sand, and obtained steel; thus demonstrating that the carbon was not furnished by the carbonic acid of the mixture, but by the gas from the furnace which penetrated through the walls of the crucible.

"Collet-Descotils and Marckensie proved that, in the same circumstances, the iron might be perfectly melted without its properties being sensibly altered.

"M. Boussingault, following rigorously the indications of Clonet, obtained a product which analysis demonstrated not to be steel, but the silicide of iron.

"Later, M. Leplay gave his ingenious theory of the treatment of minerals in high-furnaces, which he summed up thus:—

"Carbonic oxide reduces all the compounds, and carburets all the metals which can be reduced and carburetted by cementation.

"But in the researches followed in common by MM. Laurent and Leplay, the action of carbonic oxide was found absolutely null, and their experiments had for conclusion that carburetted hydrogen is the cause of the cementation and the carbonic oxide of the deoxidation.

"Thus it appears that this has not to the present time received solution. The aim of this note is to present the evidence of the direct carburetting action of carbonic oxide on iron.

"Here is the way the experiments were made:—

"Care was taken in the first place to protect the iron which was to be converted into steel from all extraneous action, by placing it in a porcelain tube varnished on the exterior and interior. These tubes are absolutely impenetrable to the gases of the furnace.

"The carbonic oxide employed was obtained by decomposing pure oxalic acid by means of sulphuric acid equally pure. This gas was separated from the carbonic acid which accompanied it by traversing several flagons filled with a solution of potassa, and was afterwards tested by passing it through a solution of baryta which did not become turpid.

"The carbonic oxide, retaining no further trace of carbonic acid, was passed through tubes containing potassa, and then through others containing pumice stone saturated with sulphuric acid, from which it came out absolutely pure and dry to enter the porcelain tube heated to a lively red. The iron submitted to the current of the gas was a fine wire which had been carefully brightened (*decape*). At the end of two hours of calcination, the cementation was complete, and during all the time of the experiment carbonic acid was disengaged; showing that the iron had decomposed the carbonic oxide. In acquiring all the properties of steel it had fixed carbon, augmenting its weight, and had eliminated oxygen which had produced the carbonic acid.

"Notwithstanding, M. Caron has made an observation very important on the decomposition of the carbonic oxide by the silicium contained in the iron. He demonstrated that silicide of iron, over which was passed a current of carbonic oxide at the temperature of fusion of cast-iron, decomposes that gas, producing silica, which floats on the surface, and carbon, which combines with the iron, so that the cementation would be proportioned to the silicium which the iron contained, and would be null if the iron were pure.

"I have made with care an analysis of the silicium contained in the iron on which I have operated. I obtained from 10·29 grammes of iron only 0g,009 of silica, of which the silicium, in decomposing the carbonic oxide, would have been able to deposit only 0g, 00356, and of carbon 0g, 00035, while the deposit of carbon amounts to 0g, 0048, considering only the augmentation of weight. This steel also has been analysed:—3·010 grammes were heated during four hours in a current of moist hydrogen. It lost 0g, 014, and after a new treatment of four and a half hours 0g, 0015, making for eight and a half hours a total loss of 0g, 016, which represents 0g, 0053 of carbon, in the place of 0g, 0048 indicated by the augmentation of the weight.

"It follows from these numbers that the influence of the silicium on the cementation by carbonic oxide, though very real, has performed in the specimen treated a part nearly insignificant.

"It is necessary then to admit a direct action between the carbonic oxide and the iron.

"Furthermore, to dissipate all doubts on this point, I have operated on some pure iron, prepared in accordance with the directions of M. Peligot, by heating oxalate of iron in a current of hydrogen. There was calcined for about three hours in presence of carbonic oxide 1·318 grammes of this iron, which increased in weight from 0g, 00265 grammes to 0g, 0035, and carbonic acid was constantly disengaged. Admitting—which was not the case—that this iron contained silicium or foreign metals, the two simultaneous facts of the carburation and the production of carbonic acid would be impossible, since these metals would fix oxygen in place of eliminating it, and it would be necessary to explain the considerable deposit of carbon (0g, 00265) to suppose them in such quantities that their presence could not fail to be detected in the analysis.

"From these results, the cementation of iron by carbonic oxide cannot be doubtful, and the conditions in which it has been made have permitted the author to ascertain if nitrogen is indispensable to the production of steel. I caused a current of hydrogen to pass for a very long time over iron reduced to excessively fine sheets, and properly heated to remove from it any nitrogen that it might contain, as indicated by M. Fremy.

"This iron after this long treatment was heated during three hours in an atmosphere of carbonic oxide: carbonic acid was disengaged, and the iron was converted into steel. As the operation was made under shelter from the external atmosphere, and the carbonic oxide employed contained no nitrogen, I believe it safe to conclude from this cementation, as well as from that by the diamond, which I have heretofore communicated, that nitrogen is not indispensable either to the production or the constitution of steel."

CORRESPONDENCE.

THOMPSON'S ELECTRO-MAGNETIC INDUCTION MACHINE.

To the Editor of the Telegraphic Journal.

Sir,—I read with much interest what is said or advertised in your last number about Thompson's electro-magnetic induction machine; but I doubt whether Mr. Thompson has ever succeeded in obtaining electric light with his machine. It is well known that not only *tension* is required for obtaining electric light, but *quantity* at the same time, and that the induction machine does not create electricity, but simply converts quantity into tension. The only light to be obtained from the induction machine is that produced in the vacuum, and especially in Geissler's tubes, which I found to be about six times less than that of a small wax candle. That light will be increased, very likely, with the improvements made in the induction machine, but will never enter into comparison with that of the voltaic arc, obtained with sixty Grove cells.—Yours sincerely,

Paris, November 13, 1864. Un Abonné.

BONELLI'S TELEGRAPH COMPANY.

To the Editor of the Telegraphic Journal.

Sir,—A few months ago we were promised cheap telegraphy by the promoters of the Bonelli Electric Telegraph Company. Can you or any of your readers inform me what has become of this mightily-puffed project? Has it proved a failure? Has it gone the way of many other latter-day schemes? Why, sir, the Bonelli printing telegraph was talked of in all parts of the country. Every newspaper, pretty nearly, in the kingdom contained a description of the instrument, and an invitation to the public to subscribe capital to the company. Surely t'brass was raised; if not, a quantity o' siller was sunken in the attempt to establish a rival to existing telegraph companies. In the latter case, will the shareholders have to pay the piper, or were they guaranteed against any loss, in the event of the endeavour to form a company falling through?—Yours truly,

Clapham, Nov. 16, 1864. J. Whittaker.

Current Literature.—*Herapath's Railway Journal* of the 12th November, contains the report of a meeting of the Universal Private Telegraph Company, held on the 24th August, which appeared in our columns nearly three months since. Our contemporary is perhaps better late than never.

TELEGRAPHIC NEWS.

Telegraphy in New South Wales.—Plans have been submitted to the Legislature for a new telegraph and post-office at Tamworth. Plans are also prepared for a telegraph station at Wagga Wagga.

Telegraphic Progress.—The Russian telegraph from Omsk to Irkoutsk is completed—a distance of 3,285 miles. This renders the great telegraphic chain between the most westerly part of Great Britain and the most easterly part of Asia complete.

The Directors of the Central Pacific Railway Company state in their annual report that they have thirty-one miles of railroad and telegraph now in operation, and that their average monthly receipts since June have been over 16,000 dollars, while their expenses have not exceeded 3,000 dollars.

Progress in Queensland.—Mr. G. E. Dalrymple, the commander of an expedition sent out to explore the north-eastern coast of Australia, sums up the results of his explorations of the Herbert with the following remarks: —Stations have already spread down the Flinders to within 100 miles of the Gulf of Carpentaria, and will soon, by reaching its shores, give protection to the telegraphic line to India, viâ Timor and Java.

The Anglo-Indian Telegraph.—By a telegram received through Reuter's agency, dated Constantinople, 11th November (11.45 p.m.), we learn that a convention has been concluded between the British Government and the Porte for the working of the Anglo-Indian telegraph. A Turkish office will be established at Fao, where the land and submarine lines meet. One wire from Constantinople will be exclusively used for Indian messages. The tariff for a single message from Constantinople to Fao will be 22 francs 50 cents.

Theft of Telegraph Stamps.—At the Leeds Town-hall on the 8th instant, Michael Jordan was charged with having, on the 21st July last, broken into the offices of Messrs. Fowler, Steam Plough Works, Hunslet, and stolen the sum of £4 10s. in cash, and a quantity of telegraph stamps, the numbers of which had been taken when they were sold by Mr. Nelson, the local manager of the Electric Telegraph Company. They were presented at the company's office by the prisoner, and were recognised by Mr. Nelson, who immediately went to the gentleman who, as Jordan stated, had sent him to get them exchanged. The prisoner succeeded in escaping while Mr. Nelson was making inquiries. He was afterwards apprehended, and committed for trial.

United Kingdom Telegraph Company.—Mr. Andrews, secretary to the above company, writes the *Times* as follows:—"Sir,—A letter, signed 'D. W.,' appeared in your impression of the 5th instant, complaining of the non-delivery by this company of a telegraphic message. No particulars being given, some time has been necessarily employed in tracing the complaint, and the directors have just had the subject under their careful consideration. As it is impossible to secure an absolute perfectibility of working, and an equally absolute immunity from complaints, it would have been, perhaps, scarcely necessary to reply to your correspondent, were it not that his deductions from the one cause embrace the conclusion that this is 'a very badly conducted telegraph company.' The publication of this remark in your columns gives it its only importance. The directors have had the complaints gone through for the last month of entry, and they find that the average is exactly one complaint to 1,729 messages. To complete this number of transactions through the delicate machinery of the electric telegraph, with but one complaint, is, I submit, not altogether a discreditable performance. The public generally, judging from the increase in our business, does not appear to be of 'D. W.'s' opinion. For the four weeks ending the 24th October last year, 25,983 messages were received at our counters for transmission; for the four corresponding weeks this year, 50,189 messages; and the present business of the company shows a considerable increase even in these latter numbers."

MISCELLANEA.

A Company for Electric Light Fishing.—A company for deep-sea fishing, with the aid of electric light, has been founded at Dunkirk.

Money Order System in America.—The postal money order system, which has proved of so much service to the commercial community of this country, was brought into use on the other side of the Atlantic on the 1st November, and so useful has it been found already, that the *Philadelphia Inquirer* affirms that it "will soon be discovered to be indispensable in the management of business in different sections of the country."

The Proposed Exhibition at Copenhagen.—For some time past a very strong desire has been expressed that an exhibition of the manufactures and art of the Scandinavian States should be held in Copenhagen, of the same kind as those which have been held in London and elsewhere. A committee for carrying out this project was appointed, of which Prince Oscar was selected president, whose report has just been published in which it is proposed "That an exhibition of the products of the three Scandinavian States—Sweden, Norway, and Denmark—should take place in the summer of 1866, and that for that purpose a crystal palace should be constructed at the expense of the state and of the capital."

THOMPSON'S ELECTRO-MAGNETIC APPARATUS.—An abridgment of Mr. Thompson's specification will, doubtless, prove interesting to our readers. This invention has for its object the so arranging electro-magnetic induction machines as to make them suitable for use for ordinary telegraphic purposes, the machine itself making and breaking the primary battery circuit, and also working a commutator, so as to lead all the positive induced currents to one conducting wire or channel, and all the negative induced currents to another conducting wire or channel; hence, when these wires or channels are connected at a distance, a current which is practically continuous flows through them, and this current may be used for telegraphic purposes, just as a direct battery current is now commonly employed. The patentee uses two sets of induction coils, arranged end to end, and at a short distance apart. By preference he employs two, or an even number of coils in each set; but this is not essential, as a single coil may be used in place of a set. If two coils be used in each set, he connects their soft cores together at their outer ends by a permanent armature; if several coils be used in each set, he couples their cores together in pairs by permanent armatures. Between the two sets of coils he arranges an oscillating armature, which, by a rod connected with it, or otherwise, is made, as it moves to and fro, to send the primary current first into the primary wires of one set of induction coils, and then into the primary wires of the other set of coils. The oscillating armature also moves the commutator, by which the currents induced in the secondary wire of the induction coils, which are reversed by the changing the primary current from one set of coils to the other, are, nevertheless, caused to pass from the machine always in the same direction, the contacts being changed by the commutator to compensate for the changes in the direction of the induced currents. Thus it will be seen that both the primary and secondary currents are directed by the machine itself, so that the machine is self-acting, for as soon as the primary current is allowed to flow, one set of induction coils is thereby magnetised, and the oscillating armature is drawn towards this set; then, as this motion cuts off the primary current from the first set of coils, and turns it over to the other set, those in turn draw back the oscillating armature, which is thus kept in constant motion so long as the primary current is on.

THE NOVEMBER STAR SHOWERS.—Mr. H. Newton has commenced in the *American Journal of Science* the printing of the original accounts, in various languages, of the displays in former times of what may be considered the predecessors of the great exhibition of shooting stars on the morning of November 13, 1833, which afford data for the determination of the length of the annual period, and the fifty-three year cycle. They also furnish, he says, "additional arguments (if such arguments are needed) for the theory that the shooting stars are small bodies moving originally each in its own orbit, until they come into the earth's atmosphere, were they burn for an instant and are dissipated into smoke or dust. They show that the time during which the swarm of bodies furnishing the November meteors revolve about the sun must be limited to one of five accurately-determined periods, one of which is more probable than the others. They will serve to direct future observation, and perhaps verify or correct such hypotheses as have been or may be presented." M. Baillard, in commenting on Mr. Newton's calculations, says that the group of bodies which give rise to the November shooting stars may be preceded or followed by a cloud of dust excessively fine, which, under the influence of the magnetic pole, may give rise to an aurora borealis.

A NEW USE FOR GUTTA-PERCHA.—Gutta-percha is now used to protect the feet of horses from tenderness and slipping. It is first cut into small pieces and softened with hot water, then mixed with half its weight of powdered sal ammoniac, and the mixture melted in a tinned saucepan over a gentle fire, keeping it well stirred. When required for use, it is melted in a glue-pot, the hoof is scraped clean, and the mixture is applied with a knife.

THE EARLIEST CALENDAR.—The first astronomical almanack published in Europe was entitled "Kalendarium Novum for 1475," the author and publisher of which was Johann Müller, the German mathematician.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2767. J. Henshaw, an improved method of and apparatus for signalling and giving alarm on railways.
2813. E. Richardson, improvements in means and apparatus for producing or effecting fog signals.
2826. C. Cotton and W. Nunn, improvements in apparatus for facilitating communication between passengers and guards of railway trains.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2616. J. Scarisbrick, improvements in apparatus for signalling on railway trains.
2634. W. Clark, improvements in apparatus for concentrating and distilling sulphuric and other acids, and all solutions in general.—A communication.
2638. J. Tate, an improvement or improvements in signalling on railways.

PATENTS SEALED.

1234. W. Reid, improvements in apparatus used for testing the insulation of electric telegraph wires or conductors.
1412. H. A. Bonneville, improvements in telegraphic printing apparatus.—A communication.

PATENTS WHICH HAVE BECOME VOID.

2725. W. Cook and H. Cook, improvements in printing telegraphs.
2784. G. T. Bousfield, improvements in electro-plating or depositing metals.—A communication.

NOTICES TO PROCEED.

1973. P. A. J. Dujardin, improvements in electric telegraphs.
2463. F. W. Shields, improvements in telegraphic posts.

PRICES CURRENT OF INSULATING MATERIAL.

TO CORRESPONDENTS.

R. S.—Thanks. Please favour us with a more definite address.

QUERIST.—Take a solution of nitro-muriate of gold, and add to a gill of it a pint of alcohol, then immerse the plate for about fifteen minutes.

AGENT.—The property of the United Kingdom Telegraph Company, lately destroyed by a gas explosion at Liverpool, was not insured.

J. RAWLINSON.—The paper to which you refer appeared in No. 43 of the *Telegraphic Journal*.

A. WHITE.—Very little information is procurable as to the manufacture of the Atlantic cable, but we believe the work is progressing to the satisfaction of the electrician to the Atlantic Telegraph Company.

ALPHA.—The application of magnetism to the tyres of the wheels of locomotives and carriages on railways, in order to affect their impetus, has been tried, and resulted in failure.

J. WHITTAKER.—We are unable to give you the information required. The offices of the Boncili Telegraph Company are situate in John-street, Adelphi, W.C. Address the secretary.

ENQUIRER.—The oxidation of iron does not take place in pure oxygen. The presence of other substances is indispensable to the process, which may be described as the combining of two atoms of oxygen with seven atoms of iron in an atmosphere affected by carbonic acid and water.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. SMITH & Co., Strand: J. ONWHYN, Catherine-street, Strand; Messrs. DAWSON & Co., Cannon-street, E.C.; Messrs. KENT & Co., Paternoster-row, London. Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.		£.	s.	d.
Whole page	4	4	0	Quarter page	1	7	6
Half ditto	2	10	0	Four lines and under (single col.)	0	3	6

Single Advertisements from the country must be accompanied with stamps in payment.

ON RAILWAY ELECTRIC SIGNALLING.

By W. H. Preece, Assoc. Inst. C.E.

(*Continued from page* 242.)

Having established the bell communication between the two stations, the next requirement demanded of us is that there shall be one signal to rule and protect the "down line," and another signal to rule and protect the "up line."

The fundamental principle of the "block" system is that no two following trains shall be allowed to proceed in the same direction upon the same section of line at the same time, and therefore a danger-signal must be exhibited and maintained at the station from which a train has departed, until it has been cleared out of the section of line over which it is travelling. To do this effectually this signal must be under the sole control of the signalman towards whom the train is approaching; and no accident, mechanical or electrical, must be allowed to remove this signal until the train has arrived.

The signal which is most extensively used upon other railways to effect this important demand is the deflection of the ordinary needle that is employed generally for telegraphic purposes. The needle pointing to one side signifies "*Line clear,*" to the other side "*Line blocked.*" As this is manifestly insufficient for the purpose numerous endeavours have been made to improve its uncertain and indecisive indications. One half of the face has been painted *white*, the other half *red*. The needle has been loaded with cards bearing the printed words "*Train on Line*" on a red ground, and "*Line clear*" on a white ground, which are brought alternately to view through an opening on the front of the instrument. Now, the signal which I use to denote "danger" and "all clear" to the signal man is the same as that exhibited to the driver. The actual instruments themselves are, of course, not the same: the signalman's signal is in his box, the driver's on the line; but the nature and design of the signal is similar. Thus, if the raising and lowering of a semaphore arm be used on the line to guide the driver, a miniature semaphore arm is used in the box to instruct the signalman. If the exhibition and obscuration of a disc or bar is used out-of-doors, a small disc or bar precisely similar is used indoors. If it were possible to work an out-door signal by electricity the system would be perfect; but inasmuch as the power of electricity is but circumscribed, we have not yet attained that production of force which is sufficient to actuate with any degree of certainty our exposed signals. We are, therefore, compelled to adopt the nearest approach to this, and to rely upon small electrical instruments, which direct the signalman how to exhibit his out-door signals by displaying the signals which they themselves ought to give.

The semaphore instrument which I employ is shown in the following sketches (Figs. 4 and 5). The "danger" and "all clear" signals are both illustrated. If necessary the "caution" signal could easily be added; but as this signal is gradually being abandoned on most lines, and is quite useless, if not dangerous, in the "block" system, its introduction into electric signals has not been considered advisable.

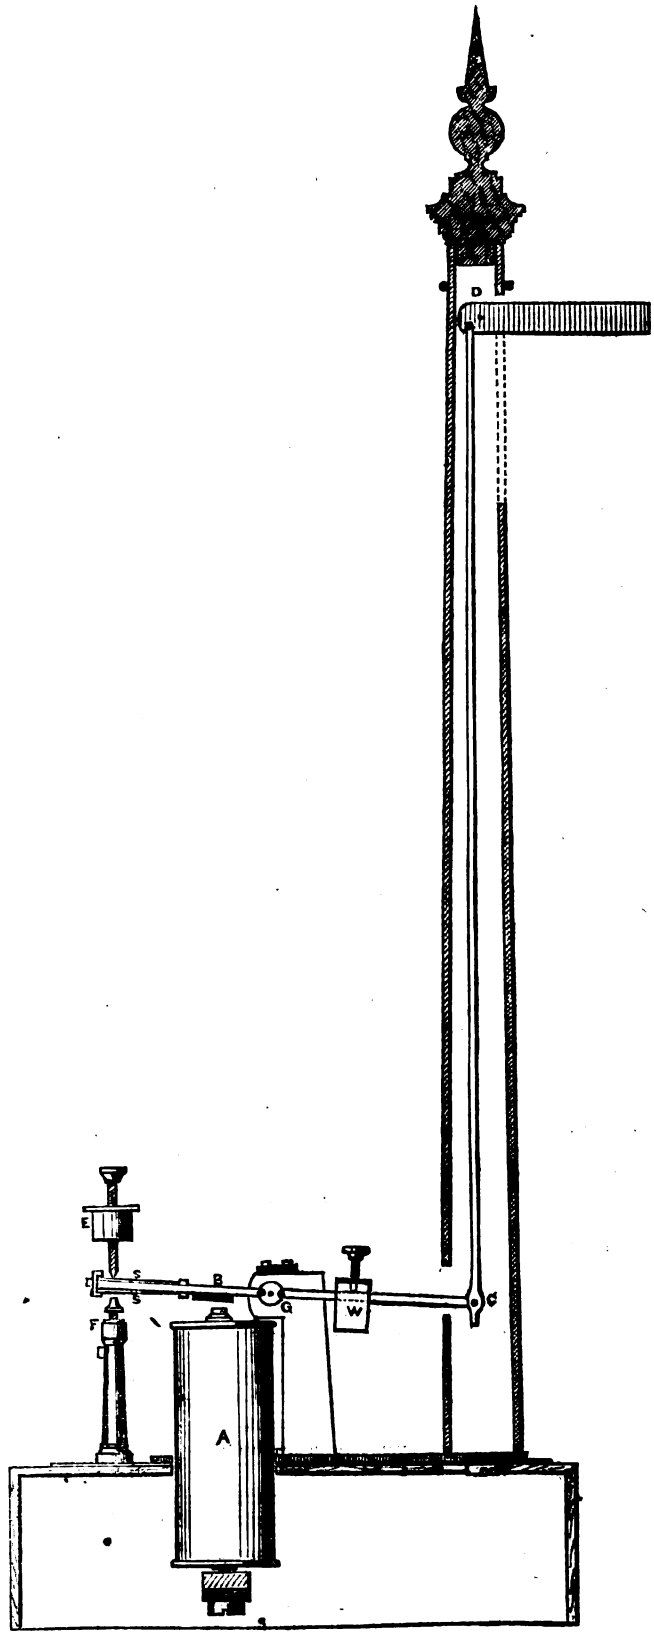

Fig. 4.

The interior mechanism of the semaphore is shown in Fig. 4, which is a complete section of one side to the scale of one-third of the full-sized instrument, but with the position of the post and arm turned sideways to make the illustrations of the working parts more clear. Fig. 5 is an end view and elevation, with the arm down and position unaltered.

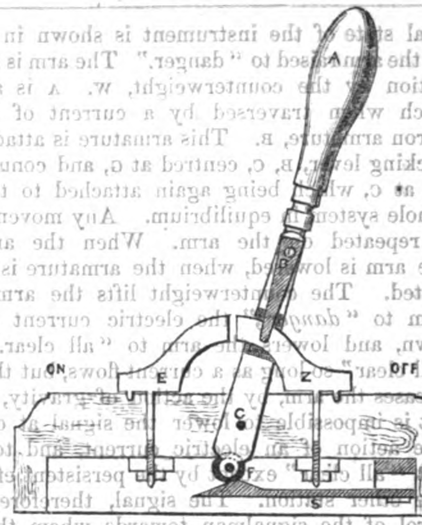

Fig. 6.

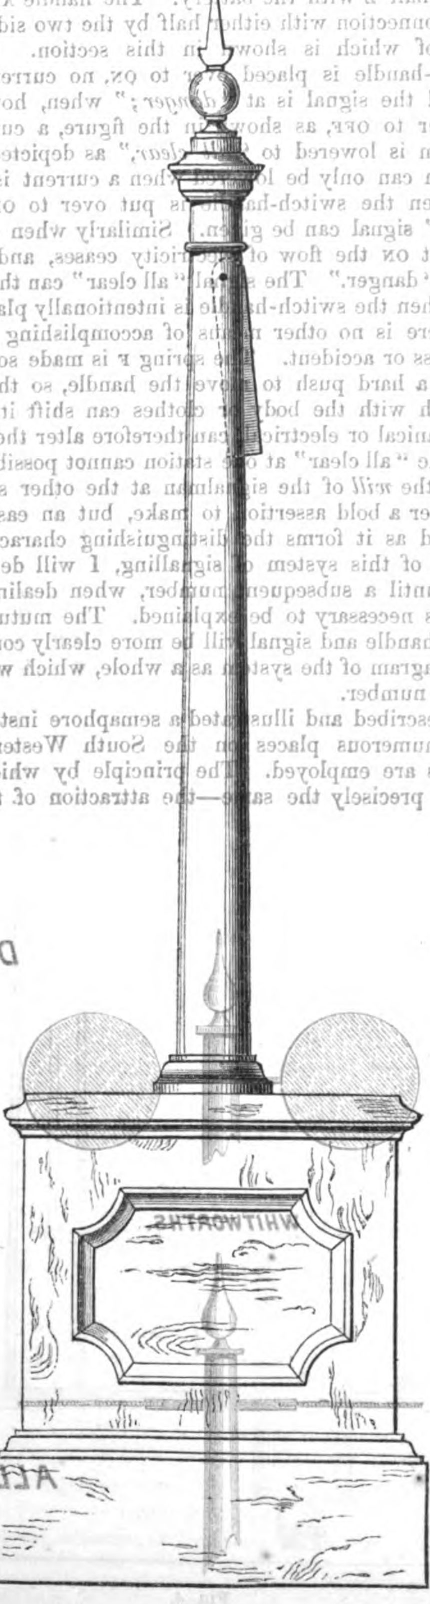

Fig. 5.

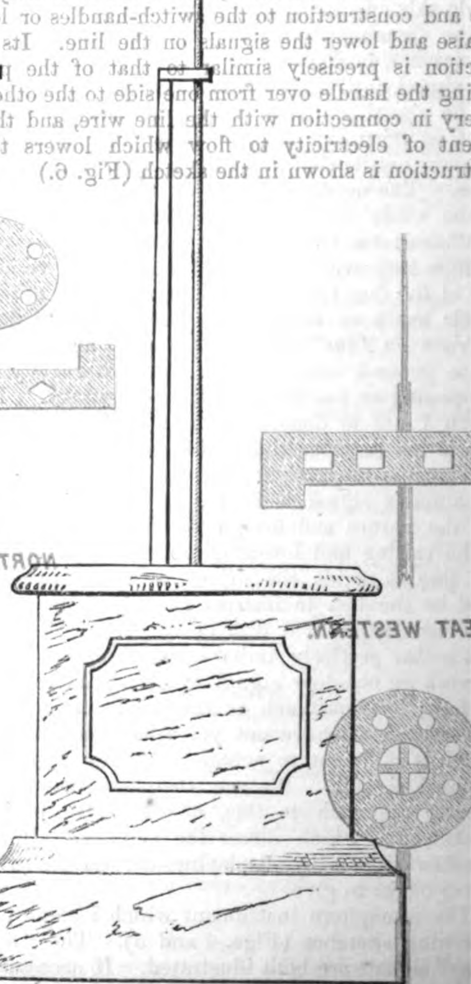

SOUTH WESTERN.

The normal state of the instrument is shown in the figure (Fig. 4) with the arm raised to "danger." The arm is maintained in that position by the counterweight, W. A is an electro-magnet, which when traversed by a current of electricity, attracts the iron armature, B. This armature is attached to the end of the rocking lever, B, C, centred at G, and connected with the rod, C, D, at C, which being again attached to the arm, D, leaves the whole system in equilibrium. Any movement of the armature is repeated on the arm. When the armature is depressed the arm is lowered, when the armature is raised the arm is elevated. The counterweight lifts the armature and raises the arm to "*danger*;" the electric current draws the armature down, and lowers the arm to "all clear." It will remain at "all clear" so long as a current flows, but the moment the current ceases the arm, by the action of gravity, flies up to "danger." It is impossible to lower the signal at one station except by the action of an electric current, and to maintain that signal at "all clear" except by the persistent effect of the battery at the other station. The signal, therefore, is under the sole control of the signalman towards whom the train is approaching.

It will be seen that the same principle which produces a blow upon the bell lowers the semaphore arm to "all clear." The current of electricity which flows through the wire of the electro-magnet converts the iron core into a magnet, and exerts precisely the same action upon the rocking lever, B, C, that a pull or strain of a signal wire does upon the rocking lever of a signal post. The counterweight, W, when the current ceases, restores the arm to "danger," as it does in ordinary line signals.

The instrument which is employed to raise and lower the signal is called a "Switch," from the similarity of its appearance and construction to the switch-handles or levers employed to raise and lower the signals on the line. Its electrical construction is precisely similar to that of the piston-key. By moving the handle over from one side to the other, it places the battery in connection with the line wire, and thereby causes a current of electricity to flow which lowers the signal. Its construction is shown in the sketch (Fig. 6.)

A is a handle which moves freely upon the centre C, S is a stout spring, with a double inclined plane, which, by pressing firmly on the friction roller F, maintains the handle in position ("blocks" it over) when it has been so moved. The semicircular piece of brass E Z is divided in the centre, to insulate the one half from the other. The half E is in connection with the earth—the half Z with the battery. The handle A is placed in electrical connection with either half by the two side-springs B, only one of which is shown in this section. Now when the switch-handle is placed over to ON, no current is transmitted, and the signal is at "*danger;*" when, however, it is pushed over to OFF, as shown in the figure, a current flows, and the arm is lowered to "*all clear*," as depicted in Fig. 5. As the arm can only be lowered when a current is flowing, it is only when the switch-handle is put over to OFF that the "all clear" signal can be given. Similarly when the switch-handle is at ON the flow of electricity ceases, and the signal must be at "danger." The signal "all clear" can therefore only be given when the switch-handle is intentionally placed over to off, and there is no other means of accomplishing this object by wilfulness or accident. The spring F is made so stout that it requires a hard push to move the handle, so that no accidental touch with the body or clothes can shift it. No accident, mechanical or electrical, can therefore alter the "danger" signal. The "all clear" at one station cannot possibly be given except by the *will* of the signalman at the other station. As this is rather a bold assertion to make, but an easy matter to explain, and as it forms the distinguishing characteristic and chief merit of this system of signalling, I will defer its consideration until a subsequent number, when dealing with the other points necessary to be explained. The mutual action of the switch-handle and signal will be more clearly comprehended from the diagram of the system as a whole, which will be given in the next number.

I have described and illustrated a semaphore instrument, but there are numerous places on the South Western Railway where discs are employed. The principle by which they are actuated is precisely the same—the attraction of the electro-

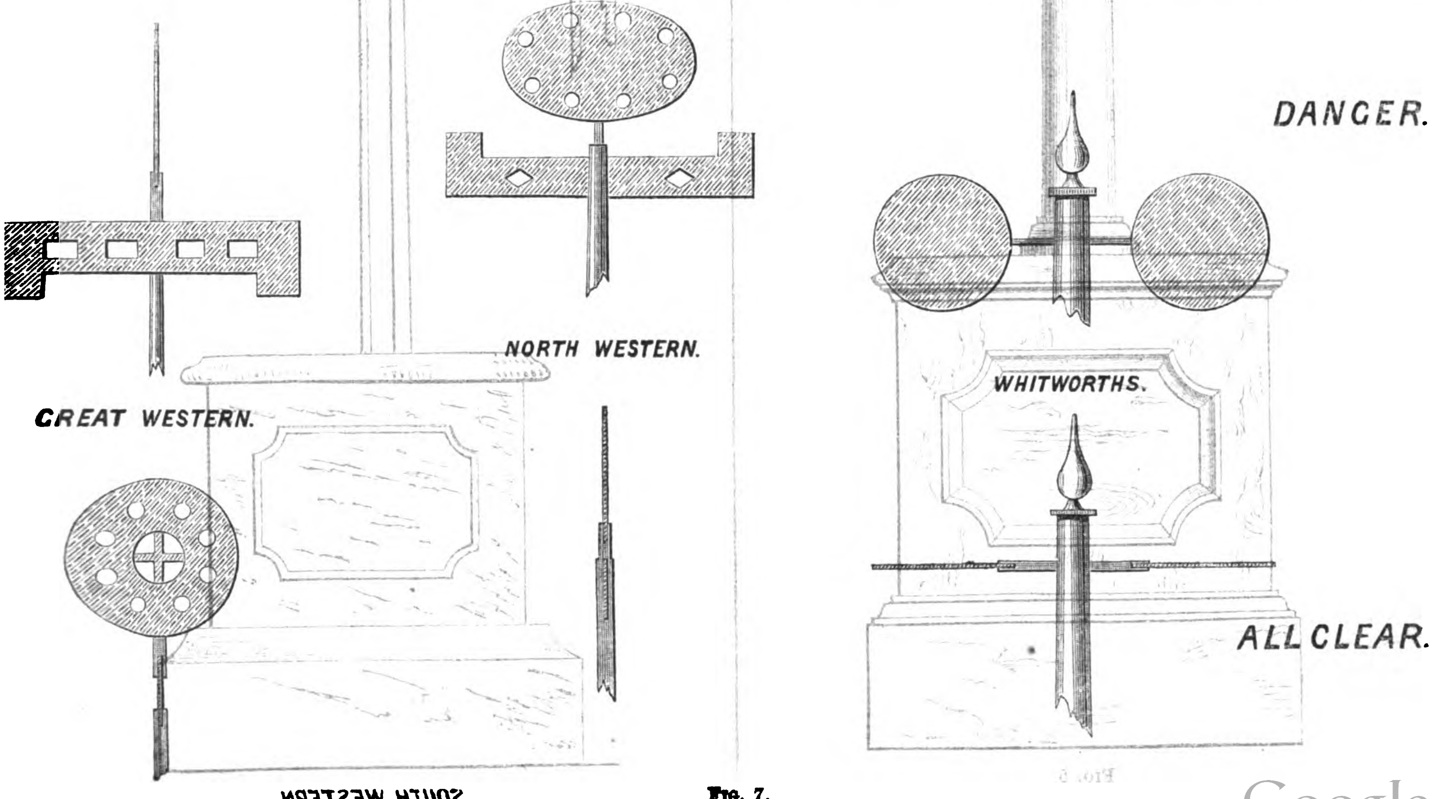

FIG. 7.

magnet is simply made to do what the strain of the wire effects upon the line. The sketches (Fig. 7) on preceding pages will fully explain this particular instrument. Gravity maintains the signal at "Danger"—the electric current takes it off. I give the sketch of an instrument working the South Western half-moon discs to the same scale as that of the semaphore, and the various discs and bars of different companies side by side. In every other respect they work the same as the semaphore.

(To be continued.)

ELECTRICAL STANDARDS AND ELECTRICAL MEASUREMENTS.

In practically dealing with dynamic electricity, the want of a standard of measure has been long felt by every one. I, with many others, have vainly hoped that ere this our learned men, who are seeking to establish such a standard, would have given us one. Either it is a difficult problem to solve, or else our *savans* do not give it the study it deserves. It is a thing requiring care, doubtless; but how it should have puzzled thirteen learned gentlemen for years, and is still unsolved by them, is not easy to understand, seeing that we find such names amongst them as Wheatstone, Varley, and Bright. One begins to think that names do not stand for much. Yet with the public these names stand for all that is, or ever can be, known in electricity. I recollect once hearing some advice given to a village schoolmaster, who was about to send out cards of what he engaged to teach. His subjects were "the three immortal R's." "Put down Latin, Greek, and Hebrew," said a gentleman whom he was consulting. "But I cannot teach these," he said. "Then charge them so high that nobody can afford to ask you; and if you can *make a show of knowing something, the people will give you credit for all that you pretend to.*" It was done, and ever after the schoolmaster was thought to be a most learned man.

It is a most mysterious thing this electricity; speaking after our *savans*, it is by turns a fluid and a force, and then again a——. Really I am puzzled; but I will quote from their report:—"Here, then, is an absolute or coherent system, starting from an effect produced by electricity when at rest." An effect, I suppose, is something done; and to be at rest is to be doing nothing. So that we have here stated that electricity has done something at the time it was doing nothing! And we are told further on that this something-nothing is work, and that it was Thomson and Helmholtz who introduced *that* into the system. Immortal Thomson and Helmholtz!

In the next paragraph we are told that the system above referred to is not that which will be found most generally useful; and to supply a system that will, we have this equation given

$$f = \frac{C L m}{k^2}.*$$

And it is said, that "from this equation it follows that the unit length of the unit current must produce the unit force on a unit pole at the unit distance." Well, that is clear enough to a certainty. But we have some more profound conclusions drawn from the equations, which embody the systems referred to. The equations are these—

$$C = \frac{E}{R}, Q = C t, W = C^2 R t, F = \frac{Q}{d^2}$$

C = current, E = electro-motive force, R = resistance, Q = quantity, W = work, t = time, F = force exerted between two charged conductors, and d = distance of those conductors.

Then follows the summation of all the relations derived therefrom:—"The unit current conveys a unit quantity of electricity through the circuit in a unit of time. The unit current in a conductor of unit resistance produces an effect equivalent to the unit of work in the unit of time. The unit current will be produced in a circuit of unit resistance by the unit electromotive force. The unit current flowing through a conductor of unit length will exert the unit force on a unit pole at a unit distance."

After all, "your committee" has not wasted its time, when it has discovered such weighty truths as these. Weighty truths—aye, truisms that there is no disputing!

The second part of the report treats of "the measurement of magnetic phenomena."

After stating that $f = \frac{m m_1}{D^2}$ we are told right off that "the dimensions of the unit magnetic pole are $\frac{L^{\frac{3}{2}} M^{\frac{1}{2}}}{T}$." But there is no hint at all why these are the dimensions of a unit pole, only at the other side of the leaf we are told that it is quite clear that it is so. No doubt it is! We will take it for granted; and then, when translated into ordinary language, the dimensions of a unit magnetic pole are these:—The square root of the cube of some length multiplied into the square root of some mass divided by some time or other. I should think it would take an expert to make a unit magnetic pole, even though he had these dimensions.

Again, "$f = m H$; therefore, the magnetic field of unit intensity will be that which acts with unit force on the unit pole." And the dimensions of the unit of magnetic intensity are $\frac{M^{\frac{1}{2}}}{L^{\frac{1}{2}} T}$. That is the square root of some mass divided by the product of the square root of some length into some time.

Further on, in treating of magnetic moment, we are told that "in reality we can never have a single pole entirely free, or disconnected from its opposite pole." In other words, we can never have a bar of steel with only one extremity, which is quite true, and also very obvious; but I must say it reminds me of my cousin from Cork.

Hitherto the truths enunciated in this report have been overwhelmingly convincing, and we have joyfully received them; but here is something difficult to assent to. This is it:—"When certain bodies, such as soft iron, &c., are placed in the magnetic field, they become magnetized by induction, so that the intensity of magnetization is (except when great) nearly proportionate to the intensity of the field."

I think Faraday has shown, and any one can now show, that the lines of force are diverted from all sides when soft iron is present to pass through it, without any exception. The above is put forth as a definition of the co-efficient of magnetic induction; but if it shows anything, I should say it shows magnetic conduction. Besides, what a definition! with an *almost* and an *exception* in it.

Then we are told diamagnetics, such as bismuth, are magnetized in an opposite direction to that of the field. As if bismuth could be magnetized at all in the sense that iron is magnetized; and if it cannot, then it is a simple abuse of words to talk of the magnetization of a diamagnetic.

The third part treats of the measurement of electrical phenomena; but first we are vouchsafed the definitions of current, quantity, electro-motive force, resistance. The which rejoiced us exceedingly, and we said in our heart, now we shall have solid ground whereon at least to begin; but it was a delusion, as the sequel will show:—

"*Meaning of the words 'Electric Quantity.'*—When two light conducting bodies are connected with the same pole of a voltaic battery, while the other pole is connected with the earth, they may be observed to repel one another. The two poles produce equal and similar effects. When the two bodies are connected with opposite poles, they attract one another. Bodies, when in a condition to exert this peculiar force one on the other, are said to be electrified, or charged with electricity. These words are mere names given to a peculiar condition of matter. If a piece of glass and a piece of resin are rubbed together, the glass will be found to be in the same condition as an insulated body connected with the copper pole of the battery, and the resin

* f = force exerted on the pole of a magnetic needle, m = strength of the pole, L = length of wire surrounding it, and k = radius of the coil.

in the same condition as the body connected with the zinc pole of the battery. The former is said to be positively, and the latter negatively electrified. The propriety of this antithesis will soon appear. The force with which one electrified body acts on another, even at a constant distance, varies with different circumstances. When the force between the two bodies at a constant distance, and separated by air, is observed to increase, it is said to be due to an increase in the quantity of electricity; and the quantity at any spot is defined as proportional to the force with which it acts through air on some other constant quantity at a distance. If two bodies, charged each with a given quantity of electricity, are incorporated, the single body thus composed will be charged with the sum of the two quantities. It is this fact which justifies the use of the word 'quantity.'

"Thus the quality in virtue of which a body exerts the peculiar force described is called electricity, and its quantity is measured (*cæteris paribus*) by measuring force.

"The quantity thus defined produced on two similar balls similarly circumstanced, but connected with opposite poles of a voltaic battery, is equal, but opposite; so that the sum of these two equal and opposite quantities is zero; hence the conception of positive and negative quantities.

"In speaking of a quantity of electricity, we need not conceive it as a separate thing, or entity distinct from ponderable matter, any more than in speaking of sound we conceive it as having a distinct existence. Still it is convenient to speak of the intensity or velocity of sound to avoid tedious circumlocution; and quite similarly we may speak of electricity, without for a moment imagining that any real electric fluid exists."

There is a definition for you! Does it define anything? does it explain anything? It would be difficult to point out what. "Your committee" is most infelicitous in its definitions. It begins by telling us that when two currents of electricity are flowing through two light conductors from the same pole of a battery, these conductors repel each other, and if to different poles they attract, and it is assumed that this force is in proportion to the quantity of electricity flowing through the wires. Then, after one or two questions have been answered that no sane person would think of asking, the paragraph ends with the sum substance and pith of this part of the definition—namely, "that if two bodies, charged each with a given quantity of electricity, are incorporated, the single body thus composed will be charged with the sum of the two quantities." "It is this fact which justifies the use of the word 'quantity.'" There is a conclusion for you. Does it not remind you of Tom Taylor's conclusion?—"And this accounts for the milk in the cocoa-nut!"

Well, now, suppose it does justify the *use* of the word quantity—is "your committee" justified in giving it as part of the meaning of *the word quantity?*

The only thing which even has a hint in it of the meaning of the word quantity is, *that the force exerted between two conductors having currents flowing through them is in proportion to the quantity of electricity present.*

That seems to be the meaning which "your committee" intended to convey, at least they assume to have done it somehow; for they go on to tell us some other marvellous things about this quantity—namely, that the quantities in the two opposite poles of a battery are equal, but opposite, so that when these two quantities are added together there is no quantity at all, or, as they have it, the sum of the quantities is zero. Then follows one of "your committee's" conclusions, "hence the conception of positive and negative quantities."

I would ask—Is "your committee" poking fun? What is a negative quantity? Are they dreaming in algebra? I suppose quantity means a positive measure of some magnitude, if it means anything at all; but a negative quantity—what is it? A measure of a certain magnitude, which is no magnitude, and nothing at all. Where am I? "Your committee" has fairly set me upon my head, and they appear to me to be all upside-down, too. I am afraid, if we go on at this rate, we shall all have to go to Bedlam together.

But this is not all. They tell us that we need not conceive of quantity of electricity as a separate thing, or entity distinct from ponderable matter, any more than in speaking of sound we conceive it as having a distinct existence. But we *do* conceive of sound as distinct from ponderable matter. It is the motion of ponderable matter made sensible to us by our ears; and surely the motion of a stone is no part of the stone.

Now comes the meaning of the words "electric current," according to "your committee":—

"When two balls charged by the opposite poles of a battery, with opposite and equal quantities of electricity, are joined by a conductor, they lose in a very short time their peculiar properties, and assume a neutral condition intermediate between the positive and negative states, exhibiting no electrical symptoms whatever, and hence described as unelectrified, or containing no electricity. But during the first moment of their junction, the conductor is found to possess certain new and peculiar properties: any one part of the conductor exerts a force upon any other part of the conductor; it exerts a force on any magnet in the neighbourhood; and if any part of the conductor be formed by one of those compound bodies called electrolytes, a certain portion of this body will be decomposed. These peculiar effects are said to be due to a current of electricity in the conductor. The positive quantity or excess is conceived as flowing into the deficiency caused by the negative quantity; so that the whole combination is reduced to the neutral condition. This neutral condition is similar to that of the earth where the experiment is tried. If the balls are continually recharged by the battery, and discharged or neutralized by the wire, a rapid succession of the so-called currents will be sent; and it is found that the force with which a magnet is deflected by this rapid succession of currents is proportional (*cæteris paribus*) to the quantity of electricity passed through the conductor or neutralized per second; it is also found that the amount of chemical action, measured by the weights of the bodies decomposed, is proportional to the same quantity. The currents just described are intermittent; but a wire or conductor, used simply to join the two poles of a battery, acquires permanently the same properties as when used to discharge the balls as above with great rapidity; and the greater the rapidity with which the balls are discharged, the more perfect the similarity of the condition of the wire in the two cases. The wire in the latter case is therefore said to convey a permanent current of electricity, the magnitude or strength of which is defined as proportional to the quantity conveyed per second."

What does "your committee" mean by all that stuff, think you? I have no doubt you can guess, if your head is not stuffed with learned nonsense; because you know they began by saying that they would explain the meaning of the words "electric current." Let me try my hand at a definition. *An electric current is the motion produced by the electric force in a conductor.* I think that is what they mean, if they did not hacker so.

"*Meaning of the words 'Electro-motive Force.'*—Hitherto we have spoken simply of statical effects; but it is found that a current of electricity, as above defined, cannot exist without effecting work or its equivalent. Thus it either heats the conductor, or raises a weight, or magnetizes soft iron, or effects chemical decomposition; in fine, in some shape it effects work, and this work bears a definite relation to the current. Work done presupposes a force in action. The immediate force producing a current, or, in other words, causing the transfer of a certain quantity of electricity, is called an electro-motive force. This force is necessarily assumed as ultimately due to that part of a circuit where a 'degradation,' or consumption of energy takes place; thus we speak of the electro-motive force of the voltaic or thermo-electric couple; but the term is also used independently of the source of power, to express the fact that, however caused, a certain force tending to do work by setting electricity in motion does, under certain circumstances, exist between two points of a conductor, or between two separate bodies. But equal quantities of electricity transferred in a given time do not necessarily or usually produce equal amounts of work; and the electro-motive force between two points, the proximate cause of the work, is defined as proportional to the amount of work done between those points when a given quantity of electricity is transferred from one point to another. Thus if, with equal currents in two distinct conductors, the work done in the one is double that done in the second in the same time, the electro-motive force in the first case is said to be double that in the second; but if the work done in two circuits is found strictly proportional to the two currents, the electro-motive force acting on the two currents is said to be the same. Defined in this way, the electro-motive force of a voltaic battery is found to be constant so long as the materials of which it is formed remain in a similar or constant condition. The above definitions, in mathematical language, give $W = E C t$, or

$$E = \frac{W}{C t}, \quad \ldots \ldots \ldots \ldots \quad (5)$$

where E is the electro-motive force, and W the work done. Thus the electro-motive force producing a current in a conductor is equal to the ratio between the work done in the unit of time and the current effecting the work. This conception of the relations of work, electro-motive force, current, and quantity, will be aided by the following analogy:—A quantity of electricity may be compared to a quantity or given mass of water; currents of water in pipes in which equal quantities passed each spot in equal times would then correspond to equal currents of electricity; electro-motive force would correspond to the head of water producing the current. Thus if, with two pipes conveying equal currents, the head forcing the water through the first was double that forcing it through the second, the work done by the water in flowing through the first pipe would necessarily be

twice that done by the water in the second pipe; but if twice as much water passed through the first pipe as passed through the second, the work done by water in the first pipe would again be doubled. This corresponds exactly with the increase of work done by the electrical current when the electromotive force is doubled, and when the quantity is doubled."

It is stated in the former part of this definition that the electro-motive force is that which causes a transfer of a quantity of electricity. Then we are told that the electro-motive force is that which does work. And immediately after we are told that equal quantities of electricity transferred in a given time do not necessarily or usually produce equal amounts of work. But how is this? Equal amounts of electro-motive force, we are told, do equal amounts of work, and it is this same electromotive force which causes the transfer of quantities of electricity, and I suppose it will take equal electro-motive forces to cause the transfer of equal quantities of electricity; yet these equal quantities do not do equal amounts of work. Surely "your committee" has a twist in its rational faculty.

To illustrate this most contradictory of definitions, we have a hydrostatic analogy given. A quantity of electricity is compared to a quantity or given mass of water. Currents of water in pipes correspond to quantities of electricity. Equal currents in equal times correspond to equal quantities of electricity. Electro-motive force corresponds to head of water. Then two pipes are supposed to convey equal currents in equal times; but one of them is supposed to have double the head or pressure that the other has. Then it is said that the work done in the first pipe will be double the work done in the second. Now, what is a current? I suppose the running of something. And for currents to be really equal, not only must the rate of that running be equal, but the quantity of that which runs must also be equal—that is, they must be equal in mass and velocity; under any other conditions no two currents can be equal. Well, then, what does "your committee" mean when they begin by supposing two currents equal, but one to have twice the head of the other? how is it possible? How can the work be double in one what it is in the other, if the currents be equal? Neither can the two currents be equal in any respect under these conditions. The only thing possible is, that the quantities delivered in equal times may be equal, if the pipe with twice the head have half the sectional area. But the currents in no respect would be equal; only the effects produced by them would be equal. Still, "your committee" is not content with this; they must make it more absurd. They say, "But if twice as much passed through the pipe that has half the pressure, then the work done would be equal." I once heard an Irish reaper ask, "Shure, sor, is this a hill all the way to the top?" "Of course, Paddy." "Thin, bi mee sowl, I wish 't had been half of it the other way; I could ha' clum it as asy agin." I should think Paddy could have settled this hydraulic paradox.

By "your committee's" definition, then, electro-motive force is that which transfers a quantity; also that which does, or is proportionate to the work done; therefore, quantity and work must be proportionate; but "your committee" says it is not necessarily so, yet they tell us in their definition of quantity that it is proportionate to the force exerted between two conductors conveying such quantity.

Then, after "your committee" imagine they have defined electro-motive force, they say:—"Thus to recapitulate, the quality of a battery, in virtue of which it tends to do work by the transfer of electricity from one point to another, is called its electro-motive force, and this force is measured by measuring the work done during the transfer of a given quantity of electricity between those points." Therefore, these three are equal, and the measure of one is the measure of all according to this; but does it agree with the foregone definitions and formula? Does $E = Q = W$? "Your committee" says "Yes" here, but in all other places "No."

And these relations have been fully explained by Professor Thomson they say. If he has explained them, it is a pity they did not quote him: it would have enhanced the value of their report somewhat.

The fourth definition is electric resistance:—

"*Meaning of the words 'Electric Resistance.'*—It is found by experiment, that even when the electro-motive force between two points remains constant, so that the work done by the transfer of a given quantity of electricity remains constant, nevertheless, by modifying the material and form of the conductor, this transfer may be made to take place in very different times; or, in other words, currents of very different magnitudes are produced, and very different amounts of work are done, in the unit of time. The quality of the conductor in virtue of which it prevents the performance of more than a certain amount of work in a given time by a given electro-motive force is called its electrical resistance. The resistance of a conductor is therefore inversely proportional to the work done in it when a given electro-motive force is maintained between its two ends."

This last definition is of a piece with the other three. After attentively reading it over a few times, one finds that it says in effect that electric resistance is that property in a conductor which causes electricity to experience resistance in passing through it; but as to what resistance may be there is no hint. Whether it be of the nature of simple friction, or of the nature of the resistance experienced by a projectile which is made up of friction and gravity, or whether it be of some other nature altogether different from these, "your committee" sayeth not.

These definitions, if one may be permitted such a stretch of language as to call them definitions, we find in the third part of this report; but they ought to have been in the first. The first thing every one does, or ought to do, who treats on a scientific subject, is to define his terms. But "your committee" first give us a lot of formula, and then attempt to define the terms they have already formulated.

They tell us that these are laws of electricity, which they have formulated. Now, I would like to know how they know that these are the laws of electricity, since it is quite clear that they have no distinct idea of what they mean by the terms they use. Read these definitions of theirs, or, as they call them, meanings of words, and see if you have any distinct idea of what they mean.

A definition ought to be short, clear, and precise. But these—why they fill a page, and that with irrelevant and often contradictory statements about something which is evidently not settled in the writer's own mind.

One would suppose that if you want to determine a standard of measure of somewhat, it would be necessary at least to have some theory about what that thing is, and how it is related to other things.

But, sir, "your sub-committee" despises theory; one of them has said as much. They are all practical men, and certainly have proved it in this report; but it is by a practical muddle. In some parts of it electricity is a fluid, then it is a force, and then again nothing at all but a kind of state in which different kinds of matter may be. Again, it is two fluids, a positive fluid and a negative fluid; and the sum of these two fluids when added together is zero, or nothing; then immediately it is a negative force and a positive force. Now, what idea is it possible to form of a negative fluid or of a negative force? If it mean no fluid or force, why, let it be so; but why make any talk at all about nothing. Talk seriously about charging a bottle with a negative quantity of wine—would any one but a lunatic? But we are seriously told in this report, that a conductor can be charged with a negative quantity of electricity.—O, but electricity is very different to wine. True, but there can be no such thing as a negative quantity of anything,—a negation is a nonentity, but a quantity is an entity. How can two opposites exist together? Certainly "your committee" did not invent these absurd terms; but they talk gravely about them, as if they understood them.

If you will have it that electricity is a fluid, then speak of it as such; if a force, let it be a force: but in the name of common sense do not talk of negative quantities of either.

We are told at the beginning that the electrical phenomena

susceptible of measurement are four in number—namely, current, force, resistance and quantity; and we are referred to this third part for the definitions of these terms. It is quite clear that the current or motion must depend upon force and counter-force, or resistance; but it is only in one sense that quantity depends upon current and time. If it be meant that there will be twice as much force exerted when a current flows two minutes as there will be if the same current flows only one minute, it may be true in that sense; but this is not the sense in which quantity has been generally used. De la Rive gives tables where the quantity and intensity of different voltaic combinations are compared. He states that a Smee's element and a Grove's element of equal size give equal quantities through small resistances; but that the Grove's will give more than three times as much through a great resistance, and this property he calls intensity or electro-motive force. Now, we all know that this is so, or at least very near the exact relations of these two elements. But time does not enter into these relations. It is merely this, that an equal effect is produced by each after overcoming a small resistance, but that the effect produced after overcoming a great resistance is three to one. Is this a delusion? "Your committee" ignores this property of a current altogether, and gives one which is not an essential property at all; it is merely a statement that two is double the number that one is. Time may be a simple term included in the complex term current, but time cannot enter into these simples here named quantity and intensity. A current must include time, for a current is a motion through space. Moreover, there can be no motion without a sufficient force to maintain it; and this motion must produce a greater or less effect on matter in its vicinity. Also the effect produced must have some relation to area as well as length: and these four properties are absolutely essential to a current. Besides this there is resistance, which relates to the conductor or medium for the current. Now as time does not enter into resistance it may be ignored in current, and it cannot enter into quantity and intensity as here set down, for they are simple qualities of a current. If this property which is here spoken of as quantity—and not only here, but by most people—is not the real quantity, then what is it? It cannot be ignored without an error in your results, for it is an essential of the phenomena. But "your committee" have ignored it, and have said that universally quantity is current multiplied by time. It may be that they will tell us that this is for static electricity, as if one law did not govern all electrical phenomena, no matter how excited. Whenever the true law is found, it will be universally applicable. But how are they to find a true law? At least, this report shows that the authors of it lacked the power to separate the like from the unlike. They have mixed up in it electric and magnetic phenomena, and spoken of them as simply electric. It is true, that electricity and magnetism are inseparably connected, the one can never appear without the other; but to thoroughly comprehend them they must be mentally separated and considered apart.

One word more as to quantity and intensity as shown by a Smee's and Grove's element.

The two produce equal results through a small resistance; and it has been therefore said that these two sources produce equal quantities.

But if the currents from these two sources be caused first to traverse equal conductors of considerable resistance, then the current from the Grove's element produces three times the result that the current from the Smee's does, and this property in the Grove's element has been called intensity; therefore it has been said of a Smee's element, when compared with a Grove's, that it gives a current of equal quantity, but of one-third the intensity, or thereabouts. This is what we are given to understand by most authors, and I venture to think that it is what most practitioners have observed. But certainly "your committee" have not represented it in their definitions or formula. The first formula put down is Ohm's.

$$C = \frac{E}{R},$$

that is, current equals electro-motive force divided by resistance. If electro-motive force be quantity multiplied by intensity, as it looks to be when comparing Grove's and Smee's, we shall have, if we represent quantity and intensity by their ratios—for Grove's, $Q = 1$ and $I = 3$ when $R = 3$; and for Smee's, $Q = 1$ and $I = 1$.

Grove's $$C = \frac{E}{R} = \frac{Q.I}{R} = \frac{1.3}{3} = 1$$

Smee's $$C = \frac{E}{R} = \frac{Q.I}{R} = \frac{1.1}{3} = \frac{1}{3}$$

Now, if $R = 0$, or very small as compared with 3, this formula is not true; for C would then $= 3$ for Grove's, and 1 for Smee's; but in this case they are equal, as proved with Hearder's magnetometer.

My learned friends, do not lift your hands; I am not going to deny Ohm's law, as it is called, just now. I merely point out a difficulty which deserves your special attention.

The second formula is $Q = Ct$. In this formula Q represents the duration of a current only as measured by its flow, and is quantity in one sense certainly; but is not universally true for currents flowing from all sources of electricity.

The same may be said of the third formula.

The fourth formula is $$F = \frac{Q}{d^2}$$

If two insulated conductors be connected with the same pole of a battery, there will be a force exerted between them; and that force, F, is equal to the quantity, Q, flowing into them, divided by the square of the distance, *d*, between them.

To measure this force, a Peltier's electrometer, or some similar instrument, is used, and it is called the *tension* of the battery, or source; but "your committee" eschew that word *tension*—it is not exact, and *they* are so very accurate!

It is said in this report that the force is directly proportionate to the quantity, but it is not, even according to "your committee's" meaning of quantity; it has nothing to do with time, neither has it anything to do with current, for the conditions are that there is no current; therefore, according to them, if $Q = Ct$, it is simply false. But this force is proportionate to that which, with due deference, I think is aptly expressed by the "inexact word" tension—not intensity, that implies a current; but tension, a straining to produce a current. It is not due to quantity, as shown by a Smee's and a Grove's battery; but by that quality which is called intensity in a current, and tension when the current is restrained from flowing. These four are the whole of the purely electric formula,—the others by-and-bye.

INDOCTUS.

THE PATENT LAWS.—It is understood that the following will be the most important recommendations to be made by the Royal Commission which has been appointed to examine and report upon the Patent Laws:—"1st. That the present system of obtaining and paying for letters patent ought to be maintained; but that patent fees should not be made to contribute to the general expenditure of the State until every reasonable requirement of the Patent Office has been satisfied. 2nd. That no patent be granted if it be found, after examination, that there has been any previous documental publication of the invention; but that no investigation be entered into concerning its merits. 3rd. That one of the judges should sit for the trial of patent cases exclusively; that he should be assisted by scientific assessors; should sit without a jury, unless the parties to the suit or action desire a jury; and when sitting without a jury, that he should decide questions of fact as well as law. 4th. That the granting of licences to use patented inventions ought not to be made compulsory. 5th. That patents ought not to be granted to importers of foreign inventions. 6th. That no patent should be extended beyond the original term of fourteen years. 7th. That the Crown should be empowered to use patented inventions without having obtained the consent of the patentee, and should pay him for such use a sum to be fixed by the Treasury."

THE ATLANTIC TELEGRAPH ENTERPRIZE.

By Amicus.

From Ireland to Newfoundland, of course. Never heard of any other Atlantic telegraph. True, there is the Larmatian scheme—a route barbarous as the country it originates in; but this goes overland mainly; and such a land! Heaven preserve our noses from coming within fifty leagues of it. But, although this knouty line is to connect Europe with America by thin respective back-doors or sink-holes, it is not an Atlantic telegraph, and so don't see why we need say any more about it; those persons who wish to be informed thereupon may consult the pages of this journal with advantage. We feel very much disposed to pass it over, but it would be disingenuous to do so; and really we can afford to be generous; besides, envy, and disingenuousness, and ungenerousness, and such-like unbecoming qualities, we impugn henceforth. Truly we are large-hearted, and at this present feel such an unbounded gush of fraternity take possession of us that we can embrace the whole world with all its rival schemes. Doubtless, some of our friends over the left will say, "It's all very well for you to make a profession of magnanimity, and swell your capacious bosoms with benevolence; but we don't believe it, and it's all because you are first in the field, and your cable is being made, &c. &c.; but there's a lot of your people who are in pain at the midriff yet, and with but a faint prospect of recovery; and you yourselves would be preciously down in the mouth and misanthropic if it were not that you think and believe your business was looking up." Pooh, man! we can afford to extend the hand of fellowship even to you, and feel a pleasure in doing so. A truce to your quibbles. It is a proof of disinterested generosity that we herewith make known that we have heard that there is another project which assumes to be an Atlantic telegraph enterprize when hatched; at present, however, it is in embryo only. This is the Borean route, and takes us through a region where Sol plays strange vagaries, grossly inconsistent with his dignity as father of a large family. The wonder is how the respectability of the establishment is kept up. Pardon the digression. If you want to know anything more about this slumbering enterprize, apply at Rue de la Luna Bisected; in the meantime we wish it success "in Greenland's icy mountains," and elsewhere. And now with respect to our more immediate object. But stay; this paper should have been numbered—No. 2—certainly, it must be, as it follows the first. Never mind; don't trouble the compositor, or his demon, or any one else now; it will be understood that this is No. 2, doubtless.

In No. 1 we said either that the cable now being made differed very materially from that of 1857-8, or that the old one differed from the new: it does not matter which; it is a mile of one, and eight furlongs of the other. Yes, it differs in size, weight, application of materials, specific gravity, external protection, and all the rest—almost. Here are heads for our discourse; let us, therefore, take a plunge. In our long clothes we adopted a No. 16 copper as our conductor—an apt type of our own puling, unfledged condition. This was like constructing the sewers of London with tobacco-pipes, or supplying the main through a goose-quill. But we are wiser now, mind you; and although we do not rigidly adhere to our friend Thomson's excellent formula $\left(200 \epsilon \left(\frac{D}{D'}\right)^2 \text{loq.} \frac{D'}{D} \right)$, we nevertheless have fixed upon a conductor much more likely to do the business than the attenuated specimen above referred to; not a solid wire—oh no, but a strand of seven wires, in which six are laid spirally round a centre one; that, however, seems unnecessary information, just as if you could twist a seven strand upon any other principle. Each of these wires has a diameter ·048 of an inch, or, as some say, ·043; perhaps it does not matter which; different peoples' diameters seem to vary as much as their gauges: it is, doubtless, what our Brummagem friends would call a No. 18. Well, and what is the advantage of having seven thin wires twisted together instead of having one solid one, or a sectional tubular one like the Persian Gulf, with the same cubical contents of metal? Much, verdant friends; the conductor of the Persian Gulf cable is a very fanciful article, and although youth is prone to be fascinated by novelties, we have wisely resolved to look shy on this importation. Advantages, quotha! why they are obvious enough. If the conductor of a single wire cable break, there is a "breach of continuity," and breaches as a rule are very bad things. And it may be submitted that a case of "breach of continuity" would be as bad as a breach of promise, a breach-loader pointed at you from one hundred paces, a breach of faith, a breach in the defences of Richmond, and a multitude of other breaches. Now, the chances are that a strand of seven wires, bend and twist it as you may, will not all break together; one may give way, but continuity is preserved; but why try to enforce that which is self-evident. You have all heard of the wise old gentleman's last will and testament, and that it consisted in this:—"My sons, see if you can break those sticks one by one." "Oh dear, yes, nothing easier." "John, my eldest born, band the fagots together; now try. Aha! you cannot;—good. Apply the moral, my children, and prosper. You are all my executors, Benedicite!" It would be insulting your well-known penetration to dwell further upon the advantages of a strand wire over a solid one; but it will have forced itself upon your perception that this has greatly the advantage over the old conductor by virtue of its being about three times the weight; this weighs some 300 lbs. per nautical mile against 107 of the old one. We are conscious of some mistake here, for which, however, we are clearly not responsible. The weight of the old conductor, if it were in No. 16 wire, would not have exceeded 75 lbs. per nautical mile, and so, at that rate, the new one will be four times the weight. "And a pretty telegraphist you must be," says some one, "not to know whether it were a No. 16 copper or no." But our extreme puerility at that time will surely extenuate what would otherwise be inexcusable haziness. Alas, friends, we were too juvenile and too much intoxicated with our brief but unparalleled success. Now, this increase of weight, like increases in bulk in general, has reference to increased capacity for doing an increase of work; this principle is really so universal as to require very little illustration. Doubtless, you remember how many tailors it takes to make a man; and that is the aptest illustration it is possible to furnish. The conductivity of a thin conductor is so nullified by induction as to render its being worked through with any comfort, for two thousand miles, extremely problematical; seeing that conductivity is as its sectional area, while inductivity is as its circumference only, it follows therefore that, although you increase its inductivity by enlarging the circumference of your conductor, you at the same time increase its conductivity at least fourfold. What is the conductivity, or more properly speaking, the measure of locomotion of a little thin wisp of a man in a dense crowd—say in Fleet-street on last illumination night? Literally nil; and yet the inductive process was awfully exhaustive. But place a six-foot bush-ranger or Leicestershire farmer, with dimensions in proportion, in the same situation. Heavens, what a seething state he would be in! His inductivity (perspiration) would be far greater than the others; but his conductivity (propulsion) would be thorough and effective, for he would pull through in time.

Tut! it is absurd to suppose we wish to practise on your credulity. We signalled at the rate of 2½ words per minute through the old cable; that you may believe or not, as you please; it is on record, and is therefore indubitably true. It follows therefore that the superior quality of the copper (its conductivity is 85° from 100° of pure copper, while the old conductor was probably on an average not more than 60°), and its quadrupled bulk, will enable us to signal at double that speed; at least, supposing no better instruments are used than were in vogue in '58. According to our talented and esteemed friend Varley's table, however, we shall speak through it at the rate of eight words per minute, and this is probably nearer the mark; indeed, it may be safely calculated upon. Then let us do a sum in arithmetic: $8 \times 60 = 480$ words per hour, and $480 \times 24 = 11{,}520$ words per day; how many for one week, a month, a year, or any other division of time, you must please work out for yourselves. Of course we shall work day and night, and make seven days every week. Our clerks and employés will have holidays, go to bed and church for all that, as we shall work upon the relay system, in more senses than one. It is in the nature of youth to be sanguine; our eating the cake, therefore, before it is baked will be excused; for the sake of brevity, however, it is a fault we should eschew.

The A1-ness of the conductor may, we think, be admitted; proceed we, then, to its dielectric. Process 1. The interior wire of the strand is handsomely coated with "Chatterton's compound;" the consequence is that when the strand is thrown up, this viscid substance is squeezed very nicely into the interstices of the strand, and thereby prevents any open space whereby water could trickle through between the conductor and insulator; now, if that is not a clever contrivance, we should be glad to be informed what is. Well, having perfected the rotundity of the conductor, excluded all the air from the crevices, secured mechanical solidity to the entire core, and at the same time lessened its inductive action,

Process No. 2 follows: that is, a coating of Chatterton's compound round the whole conductor. Then Process 3—a coating of gutta-percha—and so on alternately in a series of processes, which need not be numbered any further, until the desired thickness of insulation is attained. "But why this alternation of Chatterton's compound with gutta-percha?" asks some novice. Why, man, to make the insulation more perfect, to be sure. Suppose, when the first coating of gutta-percha is applied, there should be any small pores or what not left in it,—remedy: apply a thin coating of Chatterton's compound, and forthwith the inimitable preparation works into these minute gaps or orifices, and makes the whole as neat, and as nice, and as perfect as possible. Talk about Hughes's fluid; very good stuff, doubtless, but where's the use of it when we have a compound, the patent and working of which is held by our magnanimous friends, the Gutta-percha and Telegraph Works Company (Limited), which answers infinitely better? These admirable substances are hand and glove, and work first-rate together. Chatterton's compound is a sincere friend, who hides the defects of his ally. And gutta-percha has an affection of surpassing excellence, that casts a mantle of oblivion over a brother's nakedness. Croakers will come in here as usual, and ask, "Why use two materials when another might have been adopted which would have done the work far more effectually than the two combined?" Heigho! you are waiting for answer very likely; sorry you cannot be accommodated; the fact is, our space is exhausted, and our patience likewise. We will take your suggestions into consideration, however; think there is something in them; in the meantime, wish you success; shall have no objection to make experiments on a trial cable at your expense, and for the present beg you will accept our most distinguished consideration.

The total weight of insulation will be 400 lbs. per nautical mile, the thickness of dielectric about ·174 inch, and the total diameter of core nearly half an inch; a very nice size, indeed, neither too large nor too small, but just right, like the multifarious appurtenances of the "little, small, wee bear." True, it is not in strict conformity with Professor Thomson's formula as before observed; but bearing in mind that there is a limit to the size and weight of this cable, which circumstances necessarily enforce, it may be unhesitatingly asserted that these proportions of conductor and insulator present the most favourable that are to be found in our worthy electrician's table, which you are further entreated to remember was endorsed by the eminent mathematician above named. There is a further proof of superiority in this cable—its insulation alone being considerably heavier than the whole core of its predecessor. And when we add, what in bare justice we are bound to assert, that our friends at the Works are bestowing an amount of care, attention, and vigilance on its manufacture, &c., hitherto unprecedented, we may surely indulge in the most sanguine prospects of success. But we have not done with the core yet, although we have with its objectors for the present. Certainly not; it is tested ever and anon, or electrically examined as it comes from the manufactory, and if the lengths pass muster, they are then submerged for a day and a night in water at a temperature of 75° Fahrenheit. Not very hot certainly, but considerably more tepid than the piscatory denizens of the Atlantic would care about, and hence we may safely assume that old Neptune will not subject it to a similar ordeal when he comes into possession. This is a remarkable instance of our singular disinterestedness. We wish the cable to be tested under the most unfavourable circumstances, and so parboil it, for you all know that the insulating capacity of gutta-percha is decreased by heat; so is the discretion of man when heated by argument, his self-control when heated by passion, his wit and wisdom when heated by love, and his power of speech and locomotion when heated by wine. Besides, this parboiling process secures uniformity of condition when under test; and seeing that these tests are made at a temperature of 20° higher than the Atlantic, it allows a safe margin against disappointment at the effects of temperature after submersion, should it so turn out that the hoary god has a boiler in his kitchen, and we should be so unfortunate as to stumble on it in our route. Well, when the core has undergone this soaking, it is expected, and, indeed, does show an insulation amounting to a large but various number of millions of units, which variation depends upon whether you take "Varley's," or "Mercury," or British Association units—we refrain from the enumeration, it is an exhaustive process—this is a severe test, gentlemen, but it stands it nevertheless, and affords proof positive that the thing is being done as it should be; indeed, we don't mind stating confidentially that the least perfect part of the cable shows an insulation of double the high standard required. And then it is tested on other and various instruments of the most delicate and searching description, compared with which the discovery of a grain of gold in the Caucasus is a mere bagatelle. And then the officers of the Atlantic Company take it in hand, so that altogether it is just impossible for a defect to go undiscovered. Then, after having been wound on reels for the purpose of being subjected to the hydraulic pressure test for insulation, it is then rewound on large drums, and carefully examined inch by inch; surely a work of supererogation, we would think; but then we like to be particular, and mean to go on a safe card. And it is seriously entertained, moreover, that an apparatus be constructed which shall enable the whole cable to be examined from end to end after submersion, and that splicing and other repairs shall be conducted sub-aquæ; this by the way, however. Due notice will be given of these novelties by-and-bye. We will get the cable made and laid first; in the meantime, *sub judico lis est.*

Having been wound on these drums, the core is sent to East Greenwich to be sheathed, after which it is again subjected to the complete series of tests above described. Of course these drums, or rather their contents, are carefully secured against injury in transmission, and on their arrival at the above place, are forthwith placed in tanks filled with water, and locked up securely, as all precious and expensive commodities should be. And having got our cable thus far, perhaps we cannot do better than leave it there for the present, lest your patience be exhausted as well as ours, and there be nothing left for us to say on a future occasion. Youth will be soaring as well as sanguine, and so we shout, "Excelsior!" and bid you all join in the chorus. We will meet you again. For the present, *valete ac plaudite*, if it be not immodest.

CORRESPONDENCE.

MR. THOMPSON'S INDUCTION MACHINE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I quite agree with your Parisian correspondent that quantity, as well as tension, is required in a current of electricity to produce the electric light; but not at all when he states:—"The only light to be obtained from the induction machine is that produced in the vacuum." If he had said from induction machines similar to Rhumkorf's, it might have been true. I would ask him to suspend his judgment till he has seen mine. I have not yet had two opinions expressed upon it by those who *have* seen it.

Your correspondent speaks very positively about what an induction machine can and cannot do, as if the thing was settled and known to the very bottom. For my own part, I do not find that any one who has written on induction puts down his notions so very clearly that you can have no doubt that he understands precisely how the thing takes place; nay, I will say farther—I have not met with one who gives an understandable description of how it takes place, neither oral nor written.

I should be glad to have your correspondent's ideas on this matter. Not simply an induction machine does this, and it does not do that; but the how and the why. J. BAYNES THOMPSON.

22nd November, 1864.

THE EXPLOSION AT THE OFFICES OF THE UNITED KINGDOM TELEGRAPH COMPANY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—In the notice of the gas explosion at the United Kingdom Telegraph Company's office, Liverpool, which appeared in your valuable journal of the 12th instant, the following paragraph occurs:—"The gas had made its way through the crevices in the flooring, *and being heavier than the air*, had hung about the ground till its whereabouts was so startlingly announced upon the application of a light." Now, it appears to us that this gas is of a most mischievous character, and requires looking after. In the first place it obeys, in a very docile manner, a law of nature consistent with its specific gravity, and comes up through the crevices in the floor; but having arrived at this stage of its ramble, it suddenly turns refractory, and skulks about the floor until approached by a light, at which it immediately makes a plunge, and the result of the conflict is eternal squash to all the windows in the office.

We have been speaking to a friend of our's about the matter, and after grave deliberation he gives as his opinion that it must have been the same sort of gas that Mr. Coxwell filled his balloon with at Leicester, and which caused that unfortunate apparatus to linger "about the ground," until it got chastised with such tremendous effect by the local members of a society of gentlemen called Foresters. Of course, in mentioning this, you must understand we do not mean to imply that we entirely endorse our friend's opinion.

Our old schoolmasters used to tell us all about hydrogen and its chum, carbon: that the former was fourteen times lighter than common air, and all that sort of stuff; but of course, living as we do in the midst of such prodigious triumphs of the human mind, we naturally feel desirous to keep

as close to the heels of modern discovery as possible. We therefore beg you will request your Liverpool correspondent to favour us with a little more information about this peculiar gas, which information, we are sure, will be hailed with great delight by your numerous admiring readers, among whom will be found your devoted servants,

London, 23rd November, 1864. JOHN AND WILLIAM THOMAS.

THE ATLANTIC TELEGRAPH ENTERPRIZE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—There is an article in your journal of this week on the "Atlantic Telegraph Enterprize" by a would-be funny man, who signs himself "Amicus." It is clear that he is trying to imitate the style of some one, the spasmodic effort is so evident. I have seen writing before under the same signature, and evidently from the same pen, from many expressions common to both. I find it was on the Bath Meeting of the British Association that "Amicus" wrote before. He was not then offensive as now—nay, he even sometimes approached within sight of common-sense; but now when he wants to make believe that he is witty, he is worse than unbearable. I can only account for your putting his article in print, that you wished to hold up the mirror of his own vulgarity to him, that he might be thoroughly disgusted with himself, and eschew in future even the thought of a similar offence against decency. He appears to have mistaken slang for humour, and lower slang I should think was never before written. As to his meaning, if he has any, one cannot tell what it is. Who can bear to rake into such a heap of rubbish? It would be like groping in sewage for a farthing. BIRCH.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—There is but one step from the sublime to the ridiculous, and if ever your contributor "Amicus" found himself in the former condition, it is evident he beat a hasty retreat to a more congenial state—the state in which we behold him. In your last number "Amicus" affects to discourse on the Atlantic telegraph enterprize, but after writing the headline his spirit appears to have failed him, and he proceeds to indulge a morbid appetite for American inelegancies, to show his appreciation of the usefulness of Mr. Hotton's Slang Dictionary, and to evince his acquaintance with the national lyrics of the two countries which are about to be united by a telegraph cable across the bed of the Atlantic. Your contributor is without doubt "a verra clever person," but he lacks the good taste and common-sense so necessary to a writer who aims to address a class of enlightened readers on a subject of importance. There may have been a deal of jobbery in the arrangements which were effected a few months since between two large firms now engaged in the manufacture of the Atlantic cable; the scientific committee who reported in favour of the cable submitted by Messrs. Glass, Elliot & Co. may have been a "heterogeneous conglomerate of discordant elements;" and one member of said committee may have disavowed "all personal responsibility as to having advised this or that;" and no blame to your contributor for speaking of these things. Orderly criticism is often beneficial, but really the manner in which "Amicus" has ill treated "The Atlantic Telegraph Enterprize" is deserving of censure. He has not uttered a syllable worth a thought as to the project *per se*, but by silly exclamations, offensive interjections, and vulgar comparisons, he has sought to heap contempt upon the officials of the Atlantic Telegraph Company. If "Amicus" entertains the conviction that he can approach the understandings of those to whom he addresses himself more particularly by nonsensical palaver and puerile banter, he errs grievously. It can hardly be supposed that persons whose privilege it may be to be able correct abuses will pay any heed to a paper, be it headed with ever so startling a title, when they find at the outset a trifling with words and a pandering to low instincts unworthy a clown at one of the Surrey-side theatres. If, as your contributor suggests, the scientific committee have wittingly or unwittingly betrayed their trust, let him point out their errors, in order that they may be rectified before it be too late, not in the language of the buffoon, but in terms which will command the serious consideration of your readers. Yours truly,

Isle of Wight, 24th Nov., 1864. WALTER ELMSDALE.

SOUND AS A TIME MEASURE.—In a recent French work entitled *Traite des Mecanismes*, by M. Haton de la Goupilliere, we find described a curious and ingenious method of measuring time, which gives thousandth parts of a second. The description is substantially as follows:—Suppose it were required to measure the exact time of the descent of the hammer of a gun-lock on the nipple. The motion is so rapid that the most delicate stop-watch is at fault. A needle might be fixed to the hammer, so as in descending to mark a curve on a blackened metal plate; but still the time would be an unknown quantity. It may, however, be measured by means of a tuning-fork, also provided with a marking needle; then while the former one marks the curve described by the hammer, the second needle will mark the vibrations of the fork; and as we know that they are isochronous, each of the small insinuosities thus obtained on the blackened plate will represent a fraction of time, and show how many such fractions elapsed before the fall of the hammer. To give an idea of the degree of precision which may be obtained by this process, let us suppose the normal French tuning-fork, which will perform 896 vibrations in a second; then the duration will be 1.896th of a second; and as the greatest error that can be committed cannot exceed half a vibration, the measurement will be exact to 1.1792d of a second.

TELEGRAPHIC NEWS.

TELEGRAPHY IN VICTORIA.—Melbourne has been connected by electric telegraph with Sale, Gipp's Land.

THE LATE GALES.—Telegraphic communication in the Southern part of Italy was interrupted on Monday the 7th instant in consequence of the prevalence of stormy weather; but it was perfectly re-established on the evening of the following day.

LOSS OF A TELEGRAPH CABLE.—The cable of the Victoria extension of the Oregon and Washington Territory line of telegraph, which was intended to lay across the Straits of San Juan de Fuca, was lost with the British ship Thebes, off Cape Horn, on the voyage from London some weeks ago.

AUSTRIAN TELEGRAPHS.—From the papers recently submitted by M. Von Pleuer, Minister of Finance to the House of the Reichsrath, we gather that in the year 1862 the revenue derived by the Government from the postal and telegraphic services amounted to 16,605,673 florins.

NEW ZEALAND TELEGRAPHS.—Arrangements are now so far advanced for telegraphic communication between all the provinces of the island of Nelson, that we may calculate on seeing the electric wire in full operation during the ensuing summer. The last contract for the supply of poles has been taken. The wire and other apparati was long since ordered from England, and such portions as have not yet been landed will reach their destination very shortly.

STANDARDS OF ELECTRICAL RESISTANCE.—The following resolution was passed at the last meeting of the British Association on this subject:—"That the Committee on Electrical Standards, consisting of Professor Williamson, Professor Wheatstone, Professor W. Thomson, Professor Miller, Dr. A. Matthiessen, Mr. Fleeming Jenkin, Sir Charles Bright, Professor Maxwell, Mr. C. W. Siemens, Mr. Balfour Stewart, Dr. Joule, and Mr. C. F. Varley, be re-appointed; that Mr. Fleeming Jenkin be the Secretary, and that the sum of £100 be placed at their disposal for the purpose."

THE TELEGRAPH IN MEXICO.—Advices from America in the New York papers mention that telegraphic lines are to be established between the leading cities of Mexico, communicating by way of Texas with the United States; that another line is to connect Mexico with Yucatan; and that a submarine cable will be laid to Cuba. "In this way," it is remarked, "the city of Mexico is expected soon to be in direct and instantaneous communication with New York, Havannah, and San Francisco." As Texas, however, and the other intervening States up to the frontier of Maryland, are under the Confederate Government, it is evident that telegraphic intercourse with New York cannot be effected by that route until the conclusion of the war.

THE TELEGRAPH IN RUSSIA.—The Director of Telegraphs in Russia has received information that the wires have suffered severely from a fall of rain mixed with hail, while the thermometer marked three degrees below freezing point. The rain which fell on the wires was converted into icicles strong enough to break them. A violent wind came on, which threw down a number of the posts supporting the wires. The consequence is that the service is completely interrupted between Kharkor, Krementschug, and Bakhmut, also on the line between Krementschug and Kiev, and the line connecting Jitomir with Odessa, and the Crimea.

TELEGRAPH FROM LONDON TO CHINA.—The Russian Government have completed the public line of telegraph throughout European Russia and Siberia in Asiatic Russia to Kiakhta, the frontier town of China. Kiakhta lies to the north-west of Pekin, and is distant about 750 miles from that city. It is therefore possible to send a communication from London to the capital of China in about four days. The line from St. Petersburg to Kiakhta extends over a distance of some seven or eight thousand miles, and its completion so far is an event of great importance, not only to European merchants, but also to the different Governments whose Ministers reside in the Celestial City.

THE ATLANTIC TELEGRAPH.—There are seven copper wires to form the conductor. The entire length of the cable will be 2,300 miles, so that there is 16,000 miles of copper wire. Every portion of this copper wire is subjected to electrical tests to ascertain its conductive capacity before it is allowed to be worked up. The next step is to coat these wires with eight successive layers of the insulating material, viz:—Chatterton's compound and gutta-percha, equal to an aggregate length of 18,400 miles. This core is next covered with jute wound round it from ten strands, making 23,000 miles of jute yarn. Then comes the outer protection of the cable, formed of ten covered iron wires. The iron wires itself is 23,000 miles in length, and each wire is covered separately with five strands of tarred hemp, 135,000 miles of the latter being required, making together an aggregate length of material employed of 215,500 miles, or very nearly as much as would put ten girdles round the earth, or form a line that would almost reach from the earth to the moon.

THE SUBMARINE CABLE BETWEEN TASMANIA AND VICTORIA.—The select committee appointed by the House of Assembly to inquire whether any, and if so what, means could best be taken for the restoration of the submarine cable now lying between Tasmania and Victoria has brought up its report, in which it is stated that it would be undesirable, in a pecuniary point of view, to take any steps for the re-establishment of the present cable. The only witness examined by the committee was Mr. W. R. Falconer, the director of public works, who gave a history of the cable since its submergence. His evidence went to show that no one portion of the cable is at present in working order. The cable might be repaired but at any

considerable expense: it would be impossible to estimate the cost without a survey. He believes that great advantage would accrue to Tasmania from the renewal of telegraphic communication with Victoria, but it would not be commensurate with the outlay necessary for repairing the old cable. To lift the cable, for the purpose of selling it, would cost more than any sum it could afterwards realize. He cannot even recommend that a portion of it should be raised, if required, for laying across the river Derwent, as this might involve a greater expenditure than the cost of a new line of cable. During his examination Mr. Falconer handed in the report of Mr. M'Gowan, superintendent of telegraphs in Victoria, in reference to the leasing of the line, and repairs, the annual receipts and expenses of the line. This report was given to Captain Gilmore, when preparing to visit England, about two years ago, with a request that he would endeavour to make arrangements in England with parties to repair the line, and afterwards lease and work it. Captain Gilmore on his return from England stated verbally to Messrs. M'Gowan and Falconer that no parties he had seen in England on the subject would entertain the proposition; and he also stated that he had been informed that "it was one of the worst cables ever manufactured in England, and that it had not been made to last."

MISCELLANEA.

Royal Institution Lectures.—Professor Tyndall, F.R.S., is announced to deliver a course of twelve lectures on electricity on Tuesdays and Thursdays, commencing on the 17th January, and concluding on the 23rd February, 1865. Each lecture to begin at three o'clock.

A Definition.—An engineer has been defined by a contemporary to be a man more or less gifted with the constructive faculties, furnished with a sound education in the modern sciences, and one who has passed as much time in the work-shop as in the lecture-room.

New Quicksilver Mine.—The discovery of a quicksilver mine has just been made at New Rhonard, near Olpe, Westphalia, the yield of which promises to be large. The exploration is being vigorously pushed. During the past few weeks more than 4,000 lbs. of quicksilver have been extracted.

The Great Exhibition Building.—On Saturday, the 19th instant, the Sappers and Miners, under General Sir J. Burgoyne, Colonels Lovell and Scott, and Lieut. Knocker, continued their operations in connection with the removal of the remaining portions of the Great Exhibition building. The portion of the building to be displaced was the great octagonal tower in the Cromwell-road. The chambers were charged with about 50 lbs. of powder, in addition to a considerable quantity of gun-cotton, and at twelve o'clock the batteries were simultaneously fired by electricity, the effect being the almost instantaneous fall of the tower. The experiment was one of the most successful that has yet taken place. Owing to the proximity of the houses in Cromwell-terrace, the windows of which were filled with spectators, the utmost care had to be taken. The next and final operations of the Engineers will be directed to the removal of the grand entrance, in the Cromwell-road, where the mass of material is very great.

Dangerous Chimneys.—It is a serious question whether, in the ornamentation of large chimney tops, we do not incur great responsibility. When it is thought advisable to terminate with a handsome cup, with great projections, cramps of some metal are necessary. Now as these cramps are great conductors of the electric fluid, they become extremely dangerous. According to Sir Snow Harris, and other electricians, the gases passing up the chimney are a great means of conducting lightning, but with the metal cramps added, the worst possible arrangement is completed. During the summer alone we have had many instances of chimneys and other buildings having been struck by lightning, and all the projecting stone-work sent off, in some cases to a considerable distance, to the great danger of all those whose duties required that they should be near such erections.

Bavarian Finances.—The financial period of the country is six years. The budget once voted cannot be changed till the whole period has expired. In 1856, the first year of the seventh period, the revenue of the kingdom amounted to 83,154,571f. from indirect, the rest being the produce of the domains and monopolies of the State. The expenditure for the same year was fixed at 86,933,410f., leaving a deficit of 3,778,839f. The interest of the national debt forms 31 per cent. of the whole expenditure, the army 22½ per cent., and public instruction 2 per cent. The budget voted for the eighth period, 1861-67, estimates the receipts at 96,113,265f., and the expenditure at 97,693,254f., with a yearly deficit of 420,000f., which is to be covered by the surplus receipts of the preceding year, if there be any. The most important item of the expenditure is the interest of the public debt, 28,468,490f. on a capital of 693,960,960f. The army costs 23,971,500f. a year, and public instruction 2,421,453f. The expenses of the judicial administration are about 7,350,000f. The direct taxes, comprising those on land, buildings, property, and income, are estimated at 19,599,378f. The indirect taxes, consisting of the excise and customs duties, stamps, registration dues, and sundries, produce 38,346,730f. The monopolies of the State, such as mines, railways, the navigation of the Danube, and the electric telegraph, bring about 21,000,000f. into the treasury, and the crown lands nearly as much. A sinking fund has been instituted for the extinction of the debt; it operates yearly, but to a very small extent. Besides, the length of the financial period is opposed to any considerable movements in the state of the budget.

Quick Travelling in 1620.—"*Barnard Calvert of Andover*, rode from St *George's* Church in Southwark to Dover, from thence passed by *Barge* to *Callis*, in *France;* and from thence returned back to St. *George's* Church, the same day. This, his journey, he performed betwixt the hours of three in the morning and eight in the afternoon."—*Medulla Historæ*, 1683.

Electric Polarity.—Some new facts relating to this subject have been noted by M. Volpicelli, and reported by him to the Academy of Sciences at Paris. He says:—"It is certain, if the metallic extremity of a copper wire covered with gutta-percha be placed isolated over a dry-pile condenser, that, by making it temporarily depart from the vertical position, it will manifest positive electricity; but, if it be previously agitated, it will manifest negative electricity. I have also proved that paraffin, touched very lightly with two fingers, gives positive electricity; but when touched less delicately it manifests negative electricity. These two facts confirm the existence of electrostatic polarity in the substances, produced by a more or less energetic touch. Paraffin, mixed with Steiner's amalgam, increases the electric tension of machines. In delicate electrostatic experiments, we must absolutely remove the shellac placed between the two plates of the condenser, and replace it by two parallel threads of white silk, more or less fine, according to the circumstances of the case."

Utility of the Electric Light.—The *Courrier de Bretagne* gives an interesting account of recent experiments with the electric light at Lorient, France. The night was dark, many spectators assembled, in addition to the engineers and officers comprising a commission appointed specially by the maritime prefect. First, the great dock, in which two ships were under repair, was rendered as light as day, so that the engineers were enabled to go down into it and examine all the details of the repairs. Next a signal mast was fixed, at 700 yards from the Duchayla, and at 500 from the Panama steam frigates; the signals given by flags from the summit of the mast were rendered perfectly visible on board the two ships by means of the electric light. A third experiment caused great surprise and admiration. A diver descended 20 feet under water, and by means of the light was enabled to distinguish the decimal divisions on a scale which was sent down to him and to give proofs of it. This experiment was deemed conclusive. It is now established that an electro-magnetic machine may be permanently fixed to light large workshops, submarine works, and narrow passages into harbours. It was further observed that when the light was brought to bear on the water shoals of fish were attracted by the unusual appearance, and continued to swim around the part lighted. Eels and other fish which were at the bottom of the sea, came up to the surface.

Professor Tyndall on Luminous and Obscure Radiation begins the *Philosophical Magazine* for November. After referring to the discoveries of Sir William Herschel, Sir John Herschel, and Melloni respecting the obscure rays of the red end of the spectrum, he says—"Dr. Akin inferred, from the paucity of luminous rays evident to the eye, and a like paucity of extra-violet rays, as proved by the experiments of Dr. Miller, that the radiation from a flame of hydrogen must be mainly extra-red; and he concluded from this that the glowing of platinum wire in a hydrogen flame, as also the brightness of the Drummond light in the oxyhydrogen flame, was produced by a change in the period of vibration." Dr. Tyndall adds, that by a different mode of reasoning he arrived at the same conclusion. The present paper contains a description of his numerous experiments demonstrating the character of the radiation from a hydrogen flame under a variety of conditions, the apparatus employed, and the results obtained. We select a few of the results. Fifty experiments on the radiant heat of a hydrogen flame make the transmission of its rays through a quantity of iodine, which is perfectly opaque to light, 100 per cent. To the radiation from a hydrogen flame the dissolved iodine is therefore perfectly transparent. It is also sensibly transparent to the radiation from solid bodies heated under incandescence, and to the obscure rays emitted by luminous bodies. Professor Tyndall found that, dividing the radiation from a platinum wire raised to a dazzling whiteness by an electric current into twenty-four equal parts, one of these parts is luminous and twenty-three obscure; dividing the radiation from the most brilliant portion of a flame of coal-gas into twenty-five equal parts, one of those parts is luminous and twenty-four obscure; dividing the radiation from the electric light emitted by carbon points and excited by a Grove's battery of forty cells into ten equal parts, one of these parts is luminous and nine obscure. We have only space for the following remarkable conclusions:—"On a tolerably clear night a candle flame can be readily seen at the distance of a mile. The intensity of the electric light used by me is 650 times that of a good composite candle, and as the non-luminous radiation from the coal points which reaches the retina is equal to twice the luminous, it follows that at a common distance of a foot the energy of the invisible rays of the electric light which reach the optic nerve, but are incompetent to provoke vision, is 1,300 times that of the light of a candle. But the intensity of the candle's light at the distance of a mile is less than a 20,000,000th of its intensity at the distance of a foot; hence the energy which renders the candle perfectly visible a mile off would have to be multiplied by $1,300 \times 20,000,000$, or by 26,000,000,000, to bring it up to the intensity of that powerless radiation which the eye receives from the electric light at a good distance. Nothing, I think, could more forcibly illustrate the special relationship which subsists between the optic nerve and the oscillating periods of luminous bodies. The nerve, like a musical string, responds to the periods with which it is in accordance, while it refuses to be excited by others of vastly greater energy which are not in unison with its own."

Some Meteoric Phenomena are described by M. Lespiault in a letter read at a recent meeting of the Academy of Sciences, at Paris. On the 24th of September last, about twenty minutes after mid-day, he was with his brother in the vine grounds near Nerac, when, the heavens being perfectly clear and the air calm, suddenly they heard a detonation resembling that produced by the explosion of a distant mine, which was followed by a prolonged rolling, like that of thunder or of an approaching vehicle. The sound filled the air surrounding them and did not seem to come from any particular direction. It continued for about thirty seconds, then became feeble, and then returned to its first intensity, the total duration being about a minute. The same noise was perceived in the neighbourhood at a distance between a mile and a mile and a-half.

Imports and Exports of Quicksilver.—In the first nine months of the present year not less than 3,714,174 lbs. of quicksilver were imported into the United Kingdom. This quantity is an increase on the amount received in the same period in 1863 of 2,561,441 lbs., and on that relating to 1862 of 3,282,036 lbs. Heretofore this commodity was imported principally from Spain; but of late considerable quantites have been brought from California. The exports of this article in the nine months ended 30th September last were 2,504,921 lbs., against 1,126,533 lbs. in the corresponding period of 1863, and against 719,028 lbs. in the same time of 1862. The bulk of the shipments is sent to Mexico, Peru, India, and Australia.

Minium of Iron.—The society called the Académie Nationale, of Paris, has awarded a medal to M. de Cartier, for his preparation of Minium de fer d'Anderghem—the name of the place of manufacture in Belgium. The Société d'Encouragement and the Société Centrale des Architectes, also of Paris, have likewise reported favourably on the product. The minium of iron is said to answer all the purposes of white lead, and other preparations of the like kind, to possess more solidity, to be cheaper, to last longer, and to have an especial value in preserving iron from oxidation, and rendering the surface of wood hard. Remarkable freedom from acid or adulteration is claimed for M. de Cartier's product, which is also said to lie on iron surfaces evenly and smoothly, like a varnish, effectually excluding air.

The Hydrostatic Electrometer.—We give a concise description of Sir Snow Harris's hydrostatic electrometer, as recently perfected and improved, which has been so essential to the successful prosecution of his researches. In this instrument the attractive force between a charged and neutral disc, in connection with the earth, is hydrostatically counterpoised by a small cylinder of wood, accurately weighted, and partially immersed in a vessel of water. The neutral disc and its hydrostatic counterpoise are freely suspended over the circumference of a light wheel of 2·4 inches in diameter, delicately mounted on friction wheels, so as to have perfectly free motion, and be susceptible of the slightest force added to either side of the balance. Due contrivances are provided for measuring the distance between the attracting discs. The balance-wheel carries a light index of straw reed, moveable over a graduated quadrantal arc, divided into 90° on each side of its centre. The neutral attracting plate of the electrometer is about 1½ inch in diameter, and is suspended from the balance-wheel by a gold thread over a similar disc fixed on an insulating rod of glass, placed in connection with any charged surface, the subject of the experiment. The least force between the two discs is immediately shown by the movement of the index over the graduated arc on either direction, and is eventually counterpoised by the elevation or depression in the water of the hydrostatic cylinder suspended from the opposite side of the wheel. The divisions on the graduated quadrant correspond to the addition of small weights to either side of the balance, which stand for or represent the amount of force between attracting plates at given measured distances with given measured quantities of electricity. This arrangement is susceptible of very great accuracy of measurement.

PATENTS.

APPLICATION FOR LETTERS PATENT.

2868. G. Score and R. W. Sievier, improvements in the means of communication for railway travellers with the guard.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2423. F. N. Gisborne, improvements in the means of working electric signals for gunnery practice.
2536. L. J. Crossley, improvements in supporting and insulating overground telegraph wires.
2681. L. P. G. Bellet and C. M. P. De Rouvre, certain improvements in the application of electricity as a motive power.
2687. J. H. Simpson, improvements in electric printing for telegraphic and other purposes, and in the apparatus to be used for such purposes.
2690. J. Solomon and A. G. Grant, improvements in lamps or apparatus for burning magnesium and other metallic substances.
2712. F. J. Scott, improvements in means or apparatus for signalling between passengers and guards, or others, on railway trains.

PATENTS SEALED.

1386. W. Clark, improvements in electro-magnetic and magneto-electric apparatus, and their application as a stationary or locomotive power.
254. A. Bertsch, improvements in lightning-conductors for preventing atmospheric electricity damaging electric instruments.

PATENTS WHICH HAVE BECOME VOID.

2800. W. A. Shepard, improvements in preparing and treating gutta-percha and india-rubber.
2817. J. Fisher, improvements in apparatus for indicating or regulating the passing of railway trains.
2836. J. Davidson, improvements in apparatus for communicating between the passengers and the guard and engine-driver of railway trains.
2841. J. T. Way, improvements in obtaining light by electricity.

NOTICES TO PROCEED.

1804. H. E. F. De Briou, an improved composition for protecting and preserving metals, such as iron, copper, or zinc, used in the construction of ships, or in the protection of their sides and bottoms from oxydation and corrosion from the action of sea-water, and for protecting from corrosion all submerged substances, such as chains, anchors, cables, and every oxydable metal submerged in water or exposed to atmospheric influences.
1823. A. V. Newton, improvements in electro-telegraphic apparatus.—A communication.

TO CORRESPONDENTS.

Alfred Rowbottom.—The specific gravity of iron (pure) is 7·70; of aluminium 2·67.

Amateur.—Messrs. Singer & Co., of the Vauxhall Pottery, Vauxhall, manufacture a very useful porous cell.

J. Montgomery.—The most useful work for your purpose is Culley's "Handbook of Practical Telegraphy." London: Longman & Co., Paternoster-row. Price 7s. 6d.

E. Turner.—The phenomenon you describe is common to all sulphate batteries. Clean well with turpentine and grease the edges.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co. Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

Clerks, assistants, manipulators, and instrument makers, seeking employment &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before Seven o'Clock on Thursday evening in each week. The charges for Advertisements are—

	£.	s.	d.		£.	s.	d.

ON RAILWAY ELECTRIC SIGNALLING.

By W. H. Preece, Assoc. Inst. C.E.

(*Continued from page* 256.)

It will readily be perceived how completely this apparatus fulfils the third point detailed as a desideratum for a signalling telegraph. The man at one station has the sole and complete control over the signal at the other station, and it is impossible for him to interfere with or alter the signal in his own box. It is true that he can depress the signal with his finger, but it instantly flies back. He can tie the arm down with string, but there are acts of malice and wilfulness which no human foresight can totally remedy, but which careful arrangement can render innocuous. He cannot interfere with or alter his own signal by any movement of his own apparatus, or any accidental disturbance of his instruments. The "all clear" signal can *only* be given by the man at the other station.

To prevent the possible tampering of the signal with the hand, some instruments have been securely encased in glass, but this takes away one of their distinctive characteristics—their similarity to the signals on the line—and removes considerable responsibility from the signalman in exercising care and attention in maintaining his instrument clean and in good order. One great object that I have had in view has been the construction of an instrument which any intelligent signalman can comprehend. There is no reason why an ordinary signalman should not fully understand and attend to the instrument under his charge. He cleans his own lamps, oils his own signals, adjusts his own wires, and there is no reason why he should not do the same with his signalling instrument. As a rule, these men have plenty of shrewd sense; their intelligence is generally underrated. I have found in the majority of cases that signalmen immediately comprehend these semaphore and disc instruments. They become attached to them; they keep them in order, and, as a necessary consequence, they never fail. This is rarely, if ever, the case with needles and other instruments. I therefore place the semaphore under the charge of the signalman, and discard all glass cases. Glass cases are also presumed to be useful in maintaining the interior of the instrument free from dust and dirt, but dust and dirt are amply secured against by close-fitting brass slides and ebonite plinths to the post or pillar.

I have remarked that it is possible for a man to tie his signal down by a piece of string. It is also possible for him to neglect his duty, to disregard his signals, and to swear that the semaphore was down when it was really up. Every instrument employed in carrying on the business of a railway depends upon human action, discretion, or judgment; and when drivers are found so reckless as to rush past their signals, when pointsmen are discovered so wicked or so absent as to turn points the wrong way, when signalmen are so malicious or careless as to show "all clear" when they are instructed to give "danger," no efforts of thought, no dictates of reason, no inventions of genius, will obviate accident and produce safety. The principle that is adopted to mitigate the evils arising from the fallibility of human power upon railways, is to arrange matters so as to secure safety by the mutual and independent action of two or three different individuals leading by separate routes to one result; hence, before a driver can start his train, the station-master must ring the bell, and the guard must blow his whistle; hence, also, the safety of the train staff on single lines, where the consentaneous mistake of three men must occur before collision can arise, viz., the station-master who has charge of the staff, the guard who receives it, and the engine-driver who could not move without it. The same principle has been introduced into electric signalling, where it requires two men totally disconnected from each other to make the same error, and two instruments to fail at the same moment, to endanger the safety of the line. This is accomplished by arranging that every signal shall be properly acknowledged and repeated, and that the acknowledgment shall not only imply the due receipt of the signal sent—that the instrument has acted properly—but that it has been correctly understood and properly acted upon. This forms the fourth requirement of an electric signalling system, which will now be discussed. It is a most important point, and one upon which the whole safety of electric signalling depends. It not only secures safety, but it compensates for the loss of sight, and satisfies the mind that everything has acted properly at a distance as completely and as satisfactorily as the eye does when the same action occurs within view.

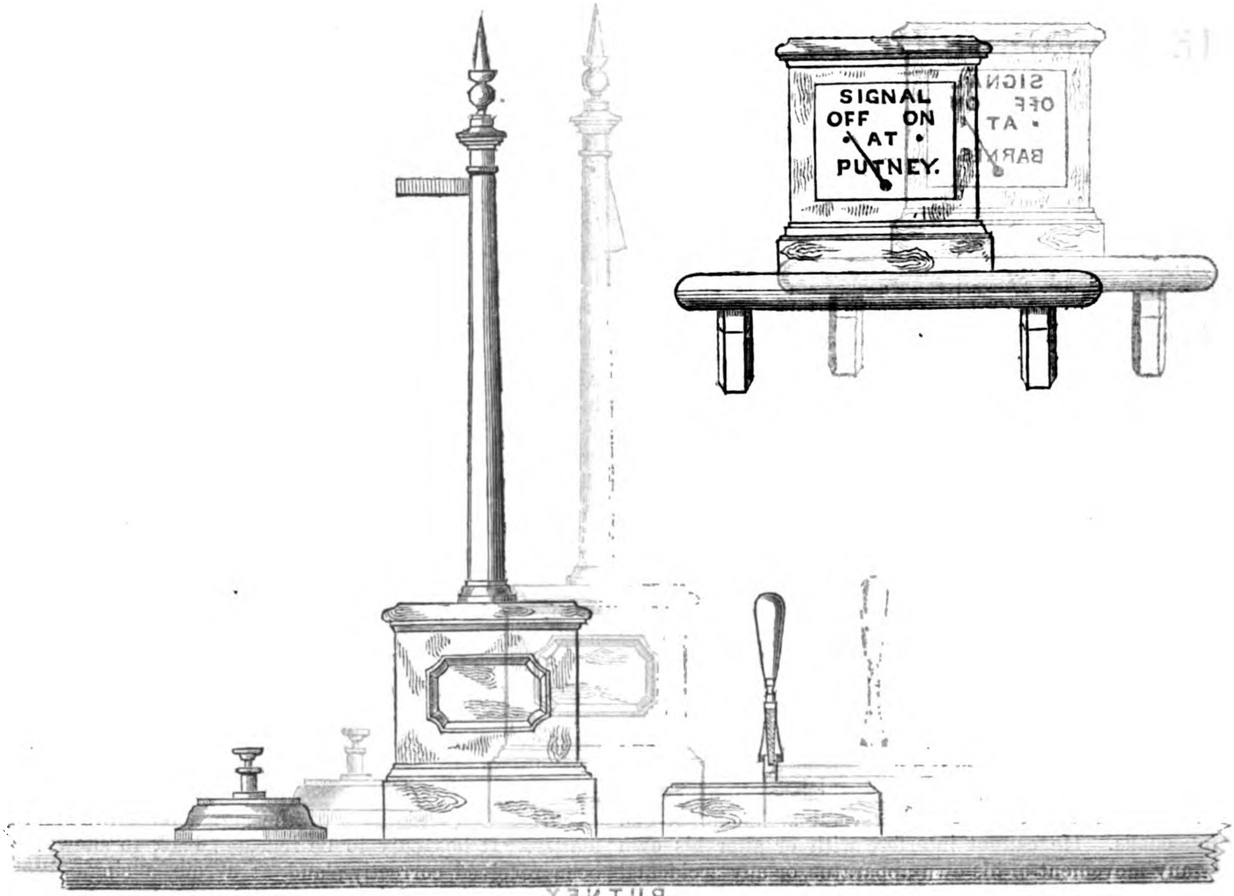
The acknowledgment of the signal on the bell is a simple matter. It has only to be repeated back to show that it has been received correctly; and, as a rule, a single beat is considered amply sufficient as an acknowledgment signal. It is, however, with the "all clear" and "danger" signals that care is necessary, repetition compulsory, and acknowledgment essential. A certain and positive knowledge that a signal has acted correctly is held to be so important by railway companies, that repeating signals, bells rung mechanically, &c., are invariably fixed when signals are unavoidably fixed out of sight. If this is held to be so important when the signal is close at hand, how much more important must it be when at a distance! Hence the greatest care has been taken in electric signals to secure repetition. Now it has been ordered that every signal received must be acknowledged, and that no signal is to be considered complete until it has been acknowledged. This acknowledgment not only implies the receipt of the signal sent, but it shows that the semaphore has acted properly, and that it is fully understood. To fully understand the action of this part of the apparatus, I append a diagram (Fig. 8, on following pages), showing the instruments fully fixed for service inside two signal-boxes at two stations, which I have called Putney and Barnes—where, indeed, they are in operation.

The semaphore at Putney, with the bell key on the one and the switch on the other side, is fixed upon the counter. The bell is placed upon a bracket above them. The same occurs at Barnes.

The wires are not shown in this diagram, because they tend so much to complicate the illustration. Suffice it to say, that the plungers and bells are fixed on one wire called the "bell wire." The semaphore at Barnes and switch at Putney on another wire, called the "Up-line wire;" and the semaphore at Putney and switch at Barnes on the the third wire, called the "Down-line wire."

It will be observed that upon the front of the case of the bell at Barnes there is fixed an indicator, which points alternately to "signal ON or OFF at Putney,"—shown on a larger

FIG. 8.



BARNES.

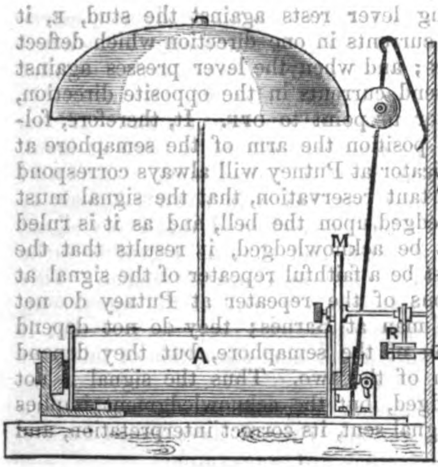


FIG. 9.

FIG. 10.

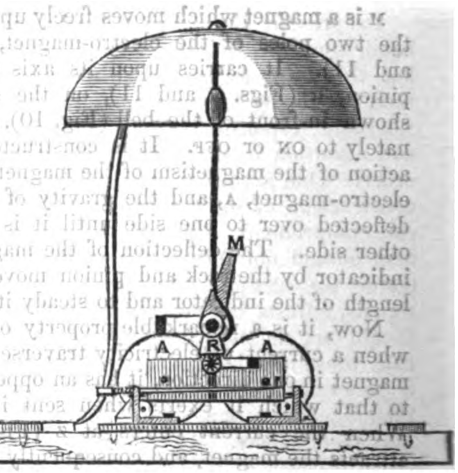

FIG. 11.

scale in Fig. 10. Now, this indicator is a faithful repeater of the signal at Putney, and it is used for no other purpose. It always indicates to the signalman at one station the condition of the signal at the other station, and always informs him of his signal having acted correctly. The contruction and details of this repeating apparatus are fully shown in Figs. 9, 10, and 11, which are respectively a side elevation, a front view of the face, and a front elevation with the face removed of the bell described in Fig. 1, but with the covering in each case taken off, and the addition of the indicating arrangement.* The principle upon which this indicator acts is more clearly shown in the following sketch (Fig. 12).

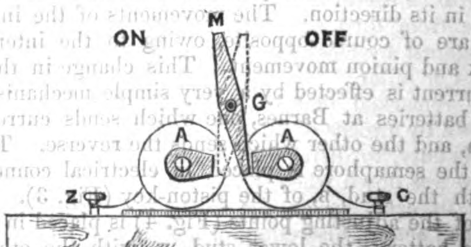

FIG. 12.

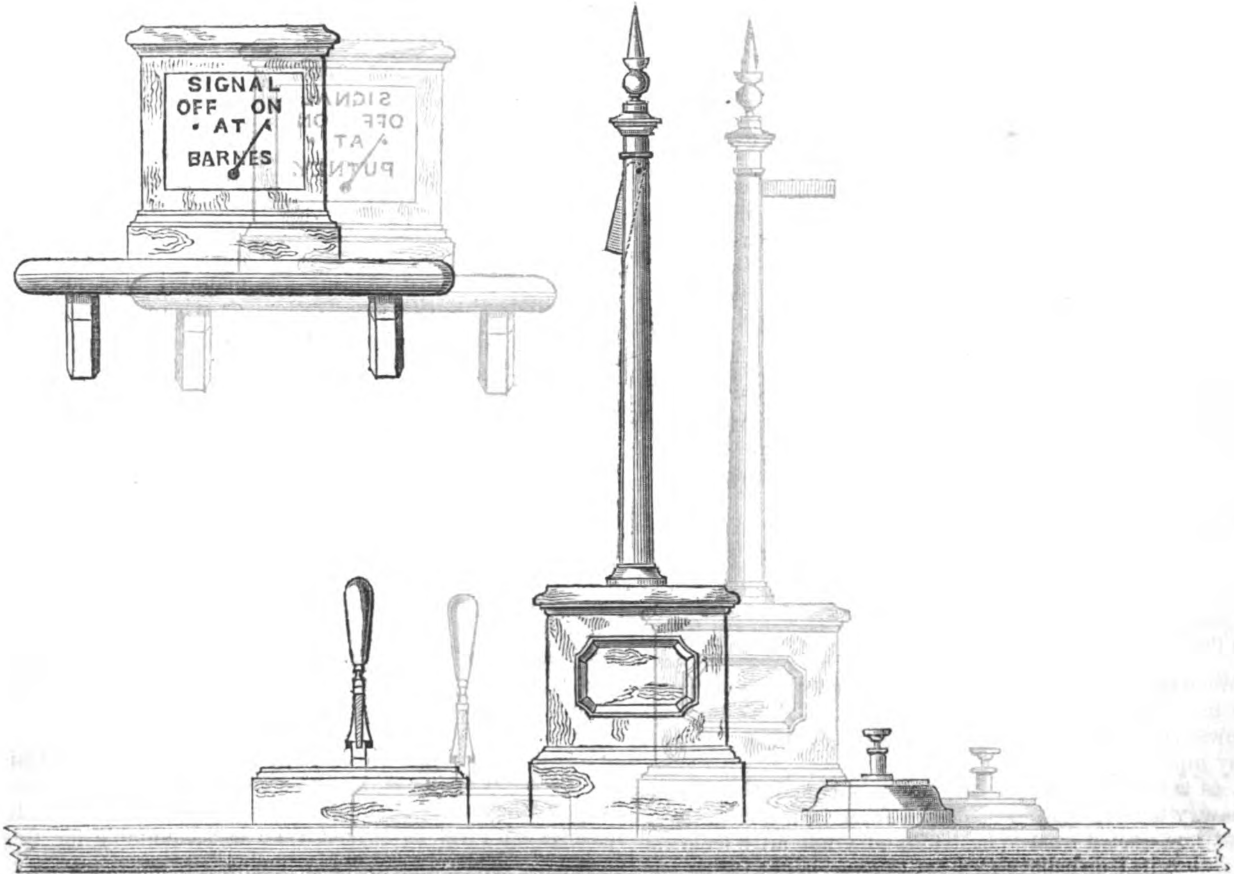
* All the illustrations in this paper, with the exception of Fig. 8, are drawn to the same scale, viz., one-third of the full size. Fig. 8 is one-sixth of the full size.

Fig. 8.



PUTNEY.

M is a magnet which moves freely upon the centre, G, between the two poles of the electro-magnet, A A, of the bell (Figs. 9 and 11). It carries upon its axis a rack, which works a pinion, R (Figs. 9 and 11), on the spindle of the indicator, shown in front of the bell (Fig. 10), and which points alternately to ON or OFF. It is constructed so that by the mutual action of the magnetism of the magnet, M, upon the iron of the electro-magnet, A, and the gravity of the indicator, it remains deflected over to one side until it is sent back again to the other side. The deflection of the magnet is transferred to the indicator by the rack and pinion movements, R, to increase the length of the indicator and to steady its movements.

Now, it is a remarkable property of electro-magnetism that when a current of electricity traverses the wire of the electro-magnet in one direction, it has an opposite effect upon a magnet to that which it exerts when sent in the contrary direction. When the current enters at Z (Fig. 12) and exits at C, it attracts the magnet, and consequently the indicator, over to ON, and it will remain pointing to ON as long as currents continue to be sent in that direction. But the moment the direction of the current is changed, the indicator flies over to OFF, and remains deflected in that position until the current is again changed in its direction. The movements of the indicator and magnet are of course opposite, owing to the interposition of the rack and pinion movement. This change in the direction of the current is effected by a very simple mechanism. There are two batteries at Barnes, one which sends currents in one direction, and the other which sends the reverse. The rocking lever of the semaphore is placed in electrical connection by a wire with the stud, B, of the piston-key (Fig. 3). The upper stud, E, of the adjusting points (Fig. 4) is placed in connection with one battery, the lower stud, F, with the other battery. Now, when the rocking lever rests against the stud, E, it enables the key to send currents in one direction which deflect the indicator over to ON; and when the lever presses against F it causes the key to send currents in the opposite direction, which cause the indicator to point to OFF. It, therefore, follows that in whatever position the arm of the semaphore at Barnes may be, the indicator at Putney will always correspond with it, with this important reservation, that the signal must have been first acknowledged upon the bell, and as it is ruled that every signal must be acknowledged, it results that the indicator at Putney must be a faithful repeater of the signal at Barnes. The indications of the repeater at Putney do not depend solely upon the man at Barnes; they do not depend upon the solitary action of the semaphore, but they depend upon the mutual action of the two. Thus the signal is not only properly acknowledged, but the acknowledgment implies the due receipt of the signal sent, its correct interpretation, and its proper instruction.

This important fact, therefore, follows, that to produce a false signal, and imperil the safety of the line, the man at Barnes must make a mistake, the semaphore at Putney must fail to act, the man at Putney must neglect his duty, and the bell and indicator at Barnes act improperly, all of which acts occurring simultaneously is far beyond the bounds of the doctrine of probabilities.

(*To be continued.*)

To Prepare Iodide of Cadmium.—Dr. Vogel says:—"Dissolve twenty-six parts of iodide of potassium and fifteen parts sulphate of cadmium in water, and condense. Heat the residue with absolute alcohol, whereby iodide of cadmium, which is easily soluble in alcohol, is separated from the sulphate of potash."—*Photographische Mittheilungen.*

"CHEROKEE" TO UNCLE SAM.

My dear uncle will excuse my delay in replying to him earlier, as he will doubtless guess that I may have been on an expedition taking scalps, as is the wont of "slashing Red Indians."

I fully agree with my uncle that f represents the strength of the current of a voltaic circuit or battery after the internal resistance of the battery is overcome.

I also agree with Wheatstone when he says, "The electromotive force of a voltaic circuit varies with the number of elements, and the nature of the metals and liquids which constitute each element." * * * * So that you see Mr. Wheatstone calls f the *electro-motive force* of a battery or circuit, composed of a "number of elements." And my uncle calls it the "*strength* (intensity) *of the current*." And I agree with them both by turns. I am no stickler for names; only if you give a thing a name stick to it.

It is the remaining part of Mr. Wheatstone's "*Law*" that I disapprove of, as not agreeing with his formula—namely, "* * * *; but is in no degree dependent on the dimensions of any of its parts."

I will state the formula again,

$$\text{“}f=\frac{nE}{\frac{nRD}{S}},$$

E, electro-motive force; R, resistance; D, distance between the plates; S, area of the plates in contact with the liquid."

Mr. Wheatstone tells us, as above quoted, that no matter how S varies, the value of f does not vary. I think any one who knows what simple division means will say it does. Am I right, my uncle?

That, as to the disagreement of the formula and Mr. Wheatstone's law, which is said to be drawn from it, my uncle says, "the first law quoted from Wheatstone may not arise from the formula;" but if I disbelieve *it*, I am to experiment for myself, and I shall find *it* true. Now, Mr. Wheatstone says his verbal law does agree with the formula, for it is drawn from the formula; and all I say is, that it does not. And my uncle seems to agree with me in the above quotation.

I never said that I disbelieved that this formula embodied a law, and that this law was true. I believe it does nearly express the work a battery can do. But Wheatstone's verbal law contradicts it, and my poor uncle does not see the contradiction.

I do not deny that the second law is true. I merely say it is "clumsily" expressed. My uncle thinks otherwise—*degustibus non est disputandem.* "Thus," says my uncle, "the first difficulty vanishes when the law and the formula are correctly stated." Of course it would, my uncle; but then "the law and the formula" are not correctly stated or they would agree, and that is what I find fault with. Oh, Sammy, Sammy! what *are* you dreaming about?

The next question, as to whether a battery will always do more work when the external and internal resistances are equal or not. My uncle is quite in the clouds again. I will restate what I said on that matter more explicitly. Given a constant external resistance, and assume that it is greater than the internal. Then, to bring up the internal resistance to the external, you must increase R or D, or both. Say we must double D to make the resistances equal. And it is said that the power of the battery to do work, or f, is increased by this operation. Let us see. First,

$$f=\frac{E}{\frac{RD}{S}},$$

when the external resistance is greater, and when we change D into 2 D to make the internal resistance equal to the external, it is said we have increased f. Now I say, and common sense says (an expression my uncle likes), that we have halved f, or made the power of the battery to do work just half what it was before, for $\frac{E}{\frac{2(RD)}{S}}$ is just half $\frac{E}{\frac{RD}{S}}$; let the multiplier 2 be any general quantity, p, and of course the result will be a diminution of power to do work. There is another condition which the Doctor has dropped out of his statement, and my uncle does not see it. With that condition the statement would approach the truth somewhat, and would then have called for no remark from me, and there would have been nothing for "my uncle" to fumble in the dark to correct.

In the next place, "my uncle" confesses he does not see what is wrong. I believe you, my wee mannie! Let me restate it. We will begin with the Doctor, or with whom ever else is responsible for it, where it is stated that $\frac{E}{R}$ represents one element or cell, and $\frac{nE}{nR}$ represents n elements or cells; by the way, I hold this as absurd and untrue; but at present it is the external resistance that is in question—namely, that a resistance, m, will lessen $\frac{E}{R}$ more than it will $\frac{nE}{nR}$, although $\frac{E}{R}=\frac{nE}{nR}$; but the Doctor says that $\frac{E}{R}-m<\frac{nE}{nR}-m$, and my uncle agrees with him.

The proper way to state this is, $\frac{E}{mR}<\frac{nE}{mnR}$; but it does not make the slightest difference, as the formula is stated to begin with. Resistances act on currents in geometric ratios, and not arithmetic; but either would do in this instance to show the absurdity, and the arithmetic is the simpler. Even this would approach the truth if the formula was properly stated, and it is the statement of it that I find fault with.

Passing over the grave fault in "my uncle," wishing to change the meaning of his expressions to suit his emergencies, though I hold that R should always mean the same as R; but he does not; yet he says, "Who is accountable for this confusion?" I merely say, "My uncle!"

My dear uncle, I am not laughing at you with my algebraical puzzle. I am simply in a fix. Will you help me out?

THE TELEGRAPH LINES IN INDIA.

From the very interesting report of the Committee of the Kurrachee Chamber of Commerce for 1863-4 we obtain the following particulars of the working of the telegraph lines in India:—

"Second only in importance to an efficient mail service is efficient telegraphic communication; and your committee regret to have to state that there has been no appreciable improvement during the year in the working of the telegraph between Kurrachee and other parts of India. In the last report of the committee allusion was made to the efforts of the Commissioner in Scinde to arouse the Supreme Government to the necessity for prompt and immediate action with regard to the state of the Electric Telegraph Department throughout India. These efforts have been continued during the year just passed, and a letter has been addressed by Mr. Mansfield to the Government of Bombay, pointing out that in eight months, from 1st October, 1862, to 31st May, 1863, telegraphic communication on the Scinde lines had been interrupted *eighty-eight times*, consuming a period of 116 days out of 243. The repeated remonstrances of the Commissioner in Scinde appear to have to some extent produced the desired effect. His letters and statistics were forwarded for report to the Director-General of Telegraphs, and on the 28th January last we find the Secretary to Government informing Colonel Douglas, in reply to his report, that Mr. Mansfield 'appears to have had good ground for complaint.' While it is matter for much regret that the Supreme Government should have been allowed to remain under the impression that the mischief occasioned by a mistaken system of centralization, and by false economy on the part of the Director-General, was attributable to a subordinate officer who is not on the spot to defend himself, it is highly satisfactory to find that the Governor-General in Council has been apparently at last awakened to the magnitude of the evil, and has expressed himself so strongly on the subject. That the Government have been so awakened is apparent from a [illegible]

5th May, 1864, from the Secretary to Government, Bombay, and addressed to the Secretary of the Chamber, inquiring whether the working of the Telegraph Department has, during the last twelve months, improved. The Secretary replied, embodying the opinions of the committee.

"It is much to be hoped that the matter will not now be allowed to drop. It is perhaps doubtful if the Chamber of Commerce can at present do more than they have done; but it remains to be seen whether their oft-repeated remonstrances, supported as they have been by the local Government, will produce the desired effect. The rapidly approaching completion of the telegraph to England, viâ the Mekran coast and the Euphrates valley, will, as has already been pointed out, soon render the line between Kurrachee and Bombay one of the most important in India; and unless the mercantile community and the Government of Bombay are prepared to see urgent telegrams of English news remain for an indefinite period in Kurrachee, owing to the inefficiency of the line, it is evident that a radical change must be at once inaugurated. The matter is important to Kurrachee, but it will soon be infinitely more so to Bombay.

"While on the subject of the telegraph it may be remarked that the commercial messages formerly supplied by Government have been discontinued during the year. An arrangement, however, has been entered into with the Bombay Chamber, by which copies of late telegrams received by them are forwarded to Kurrachee on the arrival of the Galle and Bombay mails. The utility of these telegrams has, however, been much impaired by the length of time they take in transmission, and the frequent mutilations to which they, in common with other messages, are subjected."

Comment on the foregoing report would be superfluous; all we have to say with regard to the matter is, "O, reform it altogether."

REPORT ON STANDARDS OF ELECTRICAL RESISTANCE.

(Concluded from page 247.)

It has already been shown that C and S can be obtained in absolute measure; hence the second member of equation (8) contains no unknown quantities, and, by the experiment described, the absolute resistance (R) of a wire might be determined. One curious consequence of these considerations is, that the resistance of a conductor in absolute measure is really expressed by a velocity; for, by equation (8), when $SL = C$ we have $R = V$, that is to say, the resistance of a conductor may be expressed or defined as equal to the velocity with which it must move, if placed in the conditions described, in order to generate a current equal to the product of the length of the conductor into the intensity of the magnetic field; or more simply, the resistance of a circuit is the velocity with which a conductor of unit length must move across a magnetic field of unit intensity in order to generate a unit current in the circuit. Moreover it can be shown that this velocity is independent of the magnitude of the fundamental units on which the expression of the magnetic intensity of the field or strength of the current is based, and hence that electrical resistance really is measured by an absolute velocity in nature, quite independently of the units of time and space in which it is expressed. By equation (8) we have

$$C = \frac{VSL}{R}, \text{ but by equation (1) } C = \frac{E}{R}, \text{ hence}$$

$$E = VSL; \qquad (9)$$

that is to say, the electromotive force produced between two ends of a straight conductor moved perpendicularly to its own length and to the lines of force of a magnetic field is equal to the product of the intensity of the field into the length of the conductor and the velocity of the motion; or, more simply, the unit length of a conductor moving with unit velocity perpendicularly across the lines of force of a magnetic field will produce a unit electromotive force (or difference of potential) between its two ends. This was by Weber made a fundamental equation, in place of equation (3), first shown by Thomson and Helmholtz to be consistent with Weber's electromagnetic equation. These simple and beautiful relations between inductive effects and the simple voltaic effects first described are well adapted to show the rational and coherent character of the absolute system.

The experiment last described, as a method of finding the absolute resistance of a conductor by measuring the velocity of motion of a straight wire, would be barely practicable; but it will be easily understood that we can, by calculation, pass from this simple case to the more complex case of a circular coil of known dimensions revolving with known velocity about an axis in a magnetic field of known intensity. Weber, from these elements, determined the absolute resistance of many wires; but this method requires that the intensity of the magnetic field be known; and the determination of this element is laborious, while its value, for the earth at least, is very inconstant. A method due to Professor Thomson, by which a knowledge of this element is rendered unnecessary, has therefore been adopted in the experiments of the sub-committee at King's College. In this plan a small magnet, screened from the effect of the air, is hung at the centre of a revolving coil, which is divided into two parts to allow the suspending fibre to pass freely.

By calculation it can be shown that when the coil revolves round a vertical axis, the couple exerted on a magnetic needle of the moment ml, when deflected to the angle d, will be

$$\frac{L^2 VH}{4k^2 R} ml \cos d.$$

The equal and opposite couple caused by the earth's magnetism will be $Hml \sin d$. Hence

$$\tan d = \frac{L^2 V}{4k^2 R}$$

or

$$R = \frac{L^2 V}{4k^2 \tan d} \qquad (10)$$

an equation from which the earth's magnetic force and the moment of the suspended magnet have been eliminated, and by which the absolute resistance (R) can be calculated in terms of the length, L, the velocity, V, the radius, k, and the deflection, d. The resistance thus calculated is expressed in electromagnetic absolute units, because equation (10) is a simple consequence of equations (1), (3), and (5)—fundamental equations in the electromagnetic system. The essence of Professor Thomson's method consists in substituting, by aid of the laws of electromagnetic induction, the measurements of a velocity and a deflection for the more complex and therefore less accurate measurements of work and force required in the simple fundamental equations. But, however simple in theory the method may be, the practical determination of the absolute resistance of a conductor by its means required great care and very numerous precautions,—some of an obvious character, while the need of others only became apparent during the course of the experiments.

The apparatus consisted of two circular coils of copper wire, about one foot in diameter, placed side by side, and connected in series; these coils revolved round a vertical axis, and were driven by a belt from a hand-winch, fitted with Huyghens' gear to produce a sensibly constant driving-power. A small magnet, with a mirror attached, was hung in the centre of the two coils, and the deflections of this magnet were read by a telescope from the reflection of a scale in the mirror. A frictional governor controlled the speed of the revolving coil. The details and a drawing of the apparatus are given in an Appendix and a plate at the end of the Report*; but a short account may fitly be given here of the points of chief practical importance, the difficulties encountered, and the improvements still desirable.

It is essential that the dimensions of the coil be very accurately known, that the axis round which it revolves should be truly vertical, and that, except in the coil itself, no currents affecting the position of the magnet be induced in any part of the apparatus. To measure the angular deflection the distance of the scale from the mirror is required, and the scale must be truly parallel to the mirror when the magnet is undeflected, or, in other words, when the coil is at rest. All these conditions were fulfilled without difficulty; but the scale by the reflection of which the deflections were measured was, towards the end of the experiments, found not to be very accurately divided; and although a correction for this inaccuracy has been applied in the calculations, an improvement can in future experiments be effected by the use of a more perfect scale. The magnet was suspended by a single silk fibre, eight feet long, inside a wooden case, and by suitable adjustments was brought very carefully to the centre of the coils. The whole suspended system was so screened from currents of air, and so well protected from vibration, that when the coil revolved at its full speed of 350 revolutions per minute, the reflection in the mirror was as clear and undisturbed as when the coil was at rest. The torsion of the long fibre was determined by experiment, and the slight necessary

* The Appendices to this Report will be reproduced in these columns hereafter.

corrections applied in the calculations. The Huyghens' gearing for the driving hand-winch was somewhat roughly constructed, and could certainly be improved; nevertheless there was little difficulty in maintaining a sensibly constant driving-power for twenty minutes at a time. The speed of the coil was controlled by a frictional governor of novel form, designed by Mr. Jenkin for another purpose, and lent for the experiments in question. The action of this governor, combined with that of the driving-gear, was such that in many experiments the oscillations in deflection due to a change of speed were not so great as those due to the passage of steamers in the river when all parts of the apparatus were at rest; so that the deflections during twenty minutes could be quite as accurately observed as the slightly imperfect zero-point from which they were measured. Still better results are expected with a larger governor, made specially for the apparatus, on the joint plans of Professor Thomson and Mr. Jenkin. The oscillations produced by the passage of steamers on the Thames at no great distance from the place of experiments were of very sensible magnitude; and although by carefully observing the limit of every oscillation during every experiment the error due to this cause was in great part eliminated, it is desirable that any future experiments should be conducted in some spot free from all local magnetic disturbance.

The speed of the coil was determined by observing on a chronometer the instant at which a small gong was struck by a detent released once in every hundred revolutions. Mr. Balfour Stewart's skill in this kind of observation enabled him thus to determine the velocity with great accuracy, especially as the observations frequently lasted for twenty minutes without material alteration in the speed.

Some error was apprehended in the necessary measurement of the length of the copper wire used, owing to the extension that would be caused by the strain usually required to straighten the wire. This really serious difficulty was eluded almost by accident, in a manner amusing from its simplicity. At the conclusion of the experiments, the wire to be measured was uncoiled in the museum at King's College, and lay in awkward bends on the planked floor. The straight planks formed an obvious contrast to the crooked wire, and a joint between the planks was found where the opening was just sufficient to hold the wire when pushed into this little groove. Held in this way, the wire when measured was quite straight, and yet was never stretched.

No other measurements than those already described are required by the simple theory; but this theory, as hitherto stated, stands in need of various slight corrections. The currents induced by the earth's magnetism are modified by the currents induced from the little suspended magnet, and also by the induction of the coil on itself. The force deflecting the magnet is also modified by the lateral distance of the coils from the vertical axis. An elaborate analysis of the corrections required on these grounds was made by Professor Maxwell; and to allow of these corrections, the moment of the suspended magnet was measured, and the position of every turn of the copper coil carefully observed. An experimental determination of the induction of the coil on itself, by a method due to Professor Maxwell, agreed with the calculated correction within one quarter per cent.

The resistance of the copper coil measured by these laborious experiments varied each day, and during each day, according to the temperature; and, moreover, this temperature could at no time be determined with sufficient accuracy. It was therefore intended that at each experiment a small German-silver coil, at a known temperature, should have been prepared exactly equal in resistance to the copper coil during that experiment, and these small coils were to have been kept as permanent records of the resistance of the copper coil on each occasion; but this resistance was found to vary so rapidly that the little copies could not be accurately adjusted with sufficient rapidity, and the resistance of the copper coil was therefore simply measured at the beginning and end of each experiment, in terms of an arbitrary unit. This proportional measurement was made with rapidity and precision by a new method, which, it is believed, is superior to the usual plan depending on the division or calibration of a comparatively short wire in the Wheatstone balance.

One unforeseen difficulty was caused by the change of direction of the earth's magnetic force during each experiment. Our method is indeed independent of the intensity of the earth's magnetism, but depends essentially on its direction, since it depends on the value of a deflection from the magnetic meridian. When this source of error was discovered by the continual and gradual change of zero observed, the absolute time of each experiment was noted, and a continuous correction obtained from the contemporaneous records at Kew, which agreed closely with the total changes observed at the beginning and end of each experiment. As the change of zero frequently reached three or four divisions in the course of the day, and as the whole deflection seldom exceeded 300 divisions, the importance of this correction is apparent.

The presence of stationary masses of iron does not affect the experiments injuriously, so long as the uniformity of the magnetic field in which the coil resolves is undisturbed—a point carefully tested before the experiments began; but a change in the position of iron in the neighbourhood during any experiment produces a corresponding error in the result, and the serious effect of moving very small masses of iron at a great distance from the coil was only fully appreciated in the later experiments.

When it is considered that the method described is the simplest known, the discrepancy between the few determinations hitherto made in absolute measurement will cause no surprise. The time, labour, and money required could hardly be expected to be given by any one person, and in researches of this kind the value of the co-operation secured by the committees of the Association is especially evident.

The absolute unit of the sub-committee is about eight per cent. larger than the unit as derived from a German-silver coil lately measured by Professor Weber. It is about six and a half per cent. larger than the unit as derived from a value published by Professor Weber of Dr. Siemens's mercury units. It is about five per cent. smaller than the unit as derived from coils issued by Professor Thomson in 1858, based on Jacobi's standard and a previous determination by Professor Weber. It is about five per cent. smaller than Thomson's determination from Joule's silver wire. It agrees most closely with an old determination of a copper standard made by Weber for Professor Thomson, which it exceeds by only a very small fraction.

The experiments of the sub-committee agree much better than the above one with another. Owing to the gradual improvement in the method and apparatus, the experiments of the last three days are alone considered satisfactory. On the first day the maximum deviation in six distinct experiments from their mean result was 2·4 per cent. On the second day the maximum deviation in four experiments from their mean was 1·3 per cent. On the third day the maximum deviation in five experiments from their mean was 1·15 per cent. The maximum deviation in the means of the three days' experiments from the mean of the whole is only four-tenths per cent.

These results are not unsatisfactory, and are perhaps more accurate than any measurement yet made of the relative values of heat and work—a measurement corresponding to a great extent in its nature with that undertaken by the committee. Nevertheless, considering the discrepancy of the various independent results, the committee are of opinion that it is essential that the results of the sub-committee should be checked by a fresh series of experiments with a new coil in a distinct place, when every separate measurement will necessarily be repeated. The sub-committee especially urge the repetition of the experiments, as with the improvements already enumerated, and other minor alterations, they confidently expect a considerably closer approximation to the absolute unit than they have hitherto obtained. It will be well here to remark that, according to the resolution of the committee of 1861, the coils, when issued, will not be called absolute units, but the units of the British Association; so that any subsequent improvement in experimental absolute measurement will not entail a change in the standard, but only a trifling correction in those calculations which involve the correlation of the physical forces.

It is now time to leave the question of absolute measurement, and pass to some of the other points under the consideration of the committee. Dr. Matthiessen has, by careful experiment, proved the permanence for a year at least of the electrical resistance of certain wires; but he has detected a change in others, due, apparently, to the influence of time. Certain specimens of silver, gold, and copper have varied; but other specimens of the same metals have remained constant. All the specimens of platinum and gold-silver alloy have remained constant, and all the specimens of German-silver have changed considerably. It is proposed to continue and extend these experiments, and it is much to be hoped that the defect observed in the German-silver tested will not be found common to all the varieties of this alloy, in other respects so well adapted for the construction of resistance-coils. Dr. Matthiessen found no difference in the resistance of wires of any of the above metals before and after the passage of a powerful

current transmitted through them continually for a fortnight. Dr. Matthiessen has also continued his experiments with the object of finding an alloy with a minimum variation of resistance due to change of temperature, but has been unable to produce a wire superior in this respect to the silver-platinum alloy mentioned in Appendix A of the Report of last year, as decreasing in conducting power 3·1 per cent. between 100° and 0° Centigrade. German-silver was found to decrease under the same circumstances 4·4 per cent.

The valuable experiments of Mr. Sabine, for Dr. Werner Siemens, of Berlin, on the reproduction of standards by means of mercury, although not undertaken for the committee, yet bear so directly on the subject before them that the results cannot be allowed to pass unmentioned. Dr. Siemens has conclusively proved that he can, in his laboratory, reproduce a standard by means of mercury with an error of less than 0·05 per cent. This admirable result, while it seriously affects the question of the best material for the construction and reproduction of the standard, leaves, of course, the question of the best magnitude for the standard quite untouched. Dr. Matthiessen thinks that several of the solid metals are equally fitted for the purposes of reproduction, and, if aided by the Association, is disposed to put his conviction to experimental proof. It is especially desirable that the various methods proposed should be tested by the concordance of the results obtained from a number of independent observers.

With reference to the construction of the material standard, it is proposed that the British Association units shall be represented by several equal standards made of the different metals, which, so far as our limited experience goes, show the greatest signs of constancy. Two at least of those stands would be made of mercury, in the manner proposed by Dr. Siemens. The permanent agreement between several of these standards would afford the strongest possible proof of their constancy.

Passing to other electrical measurements, the committee have to report that Professor W. Thomson has successfully constructed a material standard gauge by which electromotive force or difference of potentials can be directly measured. This instrument is founded on a measurement of the electrical attraction exerted on a small moveable portion of a large conducting-plane by another large parallel plane fixed at a constant distance, and electrified to a different potential. The force exerted is ultimately measured by the torsion of a platinum wire; but the difference of potential corresponding to any one gauge is simply indicated by the motion of an index to a sighted position. If the planes are brought sufficiently close, with a given torsion in the platinum wire, the moveable piece will be in a condition of unstable equilibrium when its index is in the sighted position, but if moved to a greater distance the equilibrium will be stable; hence, by a correct choice of the distance between the two planes, or initial torsion in the platinum wire, as compared with the difference of potential to be measured, any required delicacy of indication is obtained. The constancy of the gauge, like that of all standards, depends simply on the constancy of the materials of which it is constructed, and there is no reason to apprehend any special difficulty in the present case.

Professor Thomson has also on the same principle constructed an electrometer in which the distance between the parallel planes is made variable, and is adjusted by a micrometer-screw. The plane conductor, of which the small moveable index forms part, is in this instrument permanently maintained at a high potential by connexion with the inner coating of a Leyden jar, and the other plane is connected with the body to be tested. Calculation, confirmed by experiment, shows that in these instruments the difference of potentials between any two bodies, successively tested, is directly proportional to the difference of the distances between the parallel planes required in each case to bring the index to its sighted position. This difference of distance is the same whatever be the charge of the Leyden jar, provided only it remains constant during the comparison of the two bodies. With this limitation, the indications of the instrument may be called independent of the charge of the Leyden jar. There can be little doubt that gauges of electromotive force and electrometers, fulfilling the above conditions, will shortly become as necessary to all practical electricians as standards of resistance and sets of resistance-coils.

No progress has been made in the measurement of currents, and much remains to be done in this respect. The method already described, depending on the use of a tangent galvanometer, requires a knowledge of the horizontal force of the earth's magnetism, and is, therefore, in most cases beyond the reach of observers where greater accuracy is required than can be obtained by taking their value from the scientific almanacks. Next year it is hoped that this want may be remedied, and the present Report may fitly conclude by the enumeration of objects to be pursued by the committee, if re-appointed at the present meeting:—

1st. The experiments on the determination of the absolute unit of resistance will be continued.

2nd. Immediately on the conclusion of these experiments, equal standards, constructed of such metals as promise the greatest constancy, will be deposited at Kew, where the permanence of their equality will be rigorously tested.

3rd. Unit resistance-coils of the best known construction will be issued to the public.

4th. The experiments already begun on the permanence of the electrical resistance of wires and alloys under various circumstances will be continued and extended.

5th. The experiments on the reproduction of standards by chemical means will be continued.

6th. Experiments on the best construction of gauges of electromotive force or difference of potential, and on electrometers, will be continued.

7th. A standard galvanometer, for the measurement of currents in absolute measure, will be constructed, and electro-dynamometers for the same purpose compared with the standard instrument, and issued to the public.

8th. Experiments on the ratio between the electrostatic units and the electromagnetic units will be undertaken.

9th. Experiments will be made on the development of heat in conductors of known absolute resistance with currents of known absolute magnitude. The results of this experiment will give, by equation (3), a new and very accurate determination of the mechanical value of the unit of heat.

The conclusion of the experiments on absolute resistance, and the adoption of the absolute system as the basis of all electrical measurement, will, it is hoped, allow considerable progress to be made in most of these researches.

THE ATLANTIC TELEGRAPH ENTERPRIZE.

By AMICUS.

WE propose to make a few more remarks upon this subject, the vastness whereof, and the amount of success anticipated, will be our measure of excuse.

From this enterprize, as has probably been conjectured, we anticipate a bulk of immortality far outweighing the Olympian bestowments of that agreeable commodity, and compared with which the undying renown of warriors who have deluged whole continents with blood, whether from necessity or choice, is as a shadow that dwindles to the thinnest visible consistency. How many knights, whether one or more, it will please her most gracious Majesty to make out of the concern, it behoveth us not to conjecture; and a sense of modesty forbids our making any allusion as to the number of our esteemed friends who are worthy of the honour, or a specification of the particulars of the unparalleled services upon which such deserts may be fairly grounded. Doubtless, when the whole concern is successfully accomplished there will be a magnanimous display of royal favour, and may it be ours to be the recipients thereof. Our trans-Atlantic friends also will be equally generous in their way. Unfortunately, however, "Old Abe" and his compeers have no honours they can bestow (and this is the great fault of a republican government) that will distinguish us from the common herd of humanity, unless it be a lavish bestowment of greenbacks and an unusual length of new-spun buncombe; but while these small favours will be thankfully received, inasmuch as they will help to swell the dimensions of the aforesaid bulk, we nevertheless cannot be unconscious that to kneel before our sovereign lady, and be commanded by the dearest, and most silvery, and most musical voice that ever trilled over the lips of feminine royalty, "Rise, Sir Somebody Somebody," is the acme of human felicity, and of more value than all that the institutions of republicanism can bestow; and that a decoration whose intrinsic worth is fifty-eight pence sterling, pinned upon our coat by the immaculate apex of an immemorial monarchy of the first water, is a badge of wealth outweighing the coffers of Crœsus, an insignia before which all other honours "pale their ineffectual fires." No offence, Columbians. You are generous enough, we trust, to make allowances for the monarchical proclivities of the Britisher, and

the mania which its glittering paraphernalia produce upon the favoured dwellers beneath its Ægis. We value your friendship, with all its substantial and unsubstantial equivalents; and next to the aforesaid boons of home production, we appreciate to the utmost extent *your* meed of demonstrable hilarious favour that waits upon *our* success.

In our last paper we left the cable, or rather the core, or, more correctly speaking, such parts of the core as were made, safely locked up in huge water-cisterns down at East Greenwich, awaiting the final process of outer sheathing. This baptism by immersion of the core is a very excellent process; the insulation is preserved; and, by repeated testings, opportunities are afforded whereby any latent defect may be discovered which previous tests had failed to reveal; and, moreover, it has the advantage of a gradual initiating of the cable to its native element. O dear! if the Fates would only deal as gently by us! but no, they are capricious; and our joltings and tumbles from scenes and circumstances familiar, to ditto ditto remote and uncongenial, are sudden, impulsive, and dislocative, and not that gentle, gradual transition through the phantasmagoric slides which our slothful soul longeth for. Ah! but when we have done this business, then for the oasis and that ineffable state of content and repose better conceived than described, and which, for the want of an Orientalism, we cannot express.

We have shown clearly (to our satisfaction at least) the superiority of our conductor in quality of metal, construction, and bulk, and think we have been equally happy in our description of the insulation; it remains for us, therefore, to dwell briefly on the plan for external protection which we in our riper wisdom have decided upon. We may just revert to a matter, however, which may possibly be taken exception to by some eminent individuals with whom we should be sorry to be at loggerheads, while at the same time we are nervously anxious to avoid every scientific blunder of omission or commission which can be taken advantage of by the many clever readers of this journal, who would be pleased at the opportunity of impaling us upon the highly-polished shafts of their sarcastic wit. We are young and tender, and have many points, we fear, not yet armour-proof, and therefore have a more wholesome dread of this tall criticism than of Old Squeers' "Birch," or the milder remonstrance of the gentle swain with the euphonistic appellative. It will be said that the conduction of the old cable was not so much nullified by induction as by the resistance of the metal, owing to its inferior quality; but this great obstacle of resistance was implied in our remarks upon the low conductivity of the copper then used. It is manifest if the conductor of the old cable had had a conductivity equal to 85 per cent. of pure copper, instead of some 55 or 60 per cent., it would have been signalled through with much greater ease, assuming there were no vital defects of insulation; but on the supposition that the dielectric had been of the most perfect description, it by no means follows that the resistance of the wire would have presented insuperable obstacles to the working of the cable, although the retardation consequent thereupon rendered it extremely problematical as to its ever being, in a commercial sense, a success. But virtually it remains an open question, which was the greater agent of nullification to the conductivity of that cable, the great resistance of the inferior copper or the high inductivity, the resultant of slovenly workmanship in the application of a very bad quality of gutta-percha. The retardation from the latter cause was, doubtless, the greater of the two. It was increased in several ways, such as the want of uniform centricity of the conductor, where ever and anon a thin film of insulation only separated the copper from exterior influences.

The outer covering of the cable is, doubtless, familiar to every one, and as we proceed the superiority of the one now in process of manufacture will make itself apparent. The core, as being a precious and expensive article, upon the intactness of which the whole concern hinges, is, preparatory to sheathing, carefully embeded in a layer of soft jute yarn, saturated with a preservative compound, the nature of which, for obvious reasons, we do not make known. This yarn is wound round spirally, it being first carefully tested, and every pound rejected that is not found up to the sample in strength and other necessary qualities; this necessarily entails a vast amount of additional work and supervision, which of course entails its equivalent of so much extra expense incurred; but it is considered as money well spent, especially if it be true what some croakers say, that we are going to make the Atlantic a laboratory for a vast experiment on a problem which it were wise to conduct on a smaller scale on account of its great cost.

But here is where we differ from these venerable wiseacres, whom, nevertheless, we profoundly respect; we do not consider we are going to make a vast experiment, except in the general sense of the word, by which everything is to be esteemed experimental that is taken in hand either by nations or individuals—from the making of war to the regulation of the sale of periwinkles.

As observed in our last paper, we mean to go on a safe card, and believe we are doing so; and it is our conscientious conviction that if this cable do not turn out a success, it is simply impossible to span the Atlantic at all. And this we are bold to say is neither egotism nor bombast, but a conclusion to which every impartial individual must arrive, whether interested in the concern or not.

As a further evidence of the determination to do the thing in the best possible way, so as to reduce the chance of failure to a minimum, we may point to the extreme care exercised in the choice of the iron wire for sheathing—its quality, ductility, and strength. Every pound of this enormous mass of metal will be carefully tested, and any portion not up to the high standard required will be summarily rejected, without any regard as to whether the wire-drawers like the process or not. And, perhaps, it may not be out of place here, to refer briefly, and in a general way, to the mechanical properties of this cable as a whole. The choice was not made without due—nay, anxious and prolonged—deliberation—a deliberation, in fact, which we should do well to copy nationally and individually. To Mr. Fairbairn, the first mechanical engineer of the age, we entrusted the making of an extended series of experiments preparatory to deciding upon what description of cable should be adopted; and we take it to be a proof of our advance towards manhood that we had the good sense to do this. This eminent mechanician tested everything in connection with the requirements of a submarine cable with results alike honourable to his well-merited fame, and the vast importance of the enterprise—the well-being of which depended so much upon the correctness and elaborateness of his tests.

The wire is to be of homogenous iron ·095 inch diameter, and with strength sufficient to sustain 1,000 lbs. with scarcely any perceptible elongation; but such elongation as there is improves the quality. And three things are insisted upon in the selection of this wire—a proper care in selection, a judicious system of manipulation, and a rigid system of inspection of the manufacture; a trio of excellent conditions which might apply to a variety of things, and be adopted with general advantage. It seems almost unnecessary to say, because it has been said so many times, that ten of these wires are laid spirally round the padded core, each one being first covered with five strands of Manilla yarn saturated in the aforesaid compound, which is to be nameless. By this means strength is added to the entire cable, while at the same time the outer wires are protected from rust. The entire weight of the cable wants 4 cwt. of being double that of the old one; while the breaking strain, or its capacity for bearing its own weight in water, is rather more than double its predecessor. This cable, suspended we will say, perpendicularly in water, would bear eleven nautical miles of its own weight; the former one broke at about five miles. And it may be fairly assumed, that between Valentia and St. John's, this cable will never be required to sustain more than half its breaking strain.

And what shall we say next? we hear murmured here, there, and everywhere; they all vote iron a mistake, and pray sincerely for the sake of us and them, and those to be, known by the term posterity, that we the metal should abjure because *de facto* and *de jure*, 'tis sure to rust, is cumbersome, and therefore is but so much lumber that will bring to certain grief the cable company and chief. They argue, spiral iron wound however carefully around the core, will, when 'tis paying out, stretch, elongate, and wrap about the hapless core with iron grip; and thus the incubus will slip from off the shoulders that should bear the strain, the weight, the wear and tear, and fall upon the hapless part, and stab the cable to the heart: or, without metaphor, 'twould be a breach of continuity. Or, grant the cable we submerge successfully, they then will urge, "Your cable when it needs repairs, how will you bring it towards the stars? the iron then, without a doubt, all rust will be, inside and out, so that by virtue of the weight of this vast ponderous estate, which to the weak should be protection, will prove to be the great defection; 'twill sever when 'tis grappled, and have no more strength than rope of sand, but hang about in cumbrous mass when through the waters made to pass, until at length th' attenuated core gives up the ghost and sinks for evermore." A lamentable picture this, and one that's drawn not much amiss; but the [illegible] part's imagination, the rest is all exaggeration, which truly we [illegible]

prone to think is hardly worth the thoughts we think. But ere we draw unto a close, let's see what these wise men propose—or some of them; for 'twould our strength exhaust, and spin to a vast length this third and last of our immortal scribble, until our wit, that's wont to stream, would dribble. One says, "Use cane; O it will never rust, and certainly 'twill never turn to dust, on this side doomsday; 'twill not elongate by its own nor by any other weight." Another, "Hemp's the stuff for you, braided and eyeable to view; 'twill last till it's worn out, that's never, and takes a precious strain to sever; 'tis strong, compact, affords the best protection, does not elongate, never kinks in action." A third cries, "Sirs, try my first-class subaqueous cable sheathed with brass; 'tis strong, and durable, and bright; specific gravity is light; 'tis elegant and comely to behold—a line of light, a rope of burnished gold." Wisht, masters! we can hear no more, although there stands another score, each waiting with a spick-span cable, "the best," "the strongest," "most durable." Stay, there's our friend Nautulicus, he something has to say to us; and, to the best of our belief, 'twill be worth hearing: pray be brief. Then Nautulicus—"Worthy sirs, 'twere wise that blunders, bulls, and blurs, in this great enterprize should be avoided ere you put to sea. Old ocean is my element, I on it half my life have spent; and though I'm not so scientific as you, I'm apt to be a critic; and qualified to counsel, too, in matters where the boundless blue is to be sailed or cabled through. Your cable's altogether wrong, 'tis weak where it should be most strong; from centre to circumference it outrages our common sense. If you would guard against disasters, and spare your pockets good, my masters—the strength must in the centre be, and iron be expunged *per se;* the core no covering will require, but have your insulation higher than gutta-percha ere can make it; and to do this you must, I take it, call in friend Macintosh to make it; friend Allan, too, will not forsake it. Adopt this plan, then come to me, and I will pay it out at sea; my cylinder will do it safer than that Great Eastern—luckless chafer!" Thanks, gallant captain, we will wait until we have our cable straight, and then we will appeal to thee and also to the other three. If in your systems there is ought that's worthy of a passing thought, certes 'twill have our due consideration, and you may live to benefit the nation—perhaps the world, as we are doing now: we make you all a deferential bow.

It is quite evident we could not adopt everybody's cable; it is equally evident (to ourselves at least) that we have adopted the best that could be devised; and in this opinion we are so borne out by the testimony and approval of men of eminence, that it is surely unnecessary to insist upon it any further. It is the best possible proof that we telegraphists are rapidly attaining to the experience of a maturer life, and we rest with but few misgivings as to the ultimate result.

The Atlantic Telegraph Enterprize, however, apart from the mechanical considerations of the cable, is a majestic subject, and deserves to be treated in the statuesque style,—we hope to see it so treated ere long.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XVII.

A.D. 1841, July 7.—No. 9018.—Mallet, Robert.—"Certain improvements in protecting cast and wrought iron, and steel, and other metals from corrosion and oxidation, and in preventing the fouling of iron ships or ships sheathed with iron, or other ships, or iron buoys, in fresh or sea water. The specification, amongst other things, mentions the electro-chemical protection of ships "by the contact of zinc according to the plan suggested by Sir Humphry Davy." The improvements consist of:—

A mode of cleansing metals before alloying or coating them with other metals. A method of preserving iron by means of a triple alloy. The use of a varnish, particularly described in the specification, and all analagous compounds, "for the purpose of protecting iron or other metals from corrosion when employed in combination with a coating of the triple alloy" above alluded to, "or when used in combination with a covering of zinc, lead, or tin, or any mixture of these metals." The use of a "zoofagous," or animal-and-vegetable-life-destroying paint (composed of "drying linseed oil," red lead, sulphate of barytes, turpentine, "oxychloride of copper," hard yellow soap, common resin, and a little water) particularly described in the specification, or of any other paint possessing similar properties, either in combination with the triple alloy and varnish above alluded to, or with one of them, or separately, to prevent the fouling of ships, &c. The application of the zoofagous paint to ships, &c., "sheathed with copper and electro-chemically protected by the contact of zinc, according to the plan suggested by Sir Humphry Davy." The application of the triple alloy, the varnish, and paint, to iron or steel articles, and to ships, "whether all three or any two of them are used in combination, or they are used separately." The application of palladium for the purpose of protecting iron or steel.

A.D. 1841, July 7.—No. 9022.—Wheatstone, Charles.—"Improvements in producing, regulating, and applying electric currents," relating to:—1st. "The production of electric currents by means of magneto-electric machines." A magneto-electric machine is described and shown, in which five pairs of coils, fixed on the same axis, revolve between the dissimilar poles of six permanent horseshoe magnets, the axis passing between the poles of the magnets. The coils are fixed in different relative positions, so that "the current in any one coil" commences "before the currents in the other coils have ceased." The terminal wires of each coil are connected to insulated semicircular pieces of metal, inlaid in the axis, and springs always press upon these; by which arrangement an electric current always passes through the springs in the same direction. A proper metallic connection is made between the springs, so as to conduct the nearly continuous current thus produced to suitable binding screws. 2nd. "A means of regulating an electric current by varying the length of the circuit." First method:—A "slide," connected with one circuit wire, includes in the circuit more or less of a wire wound round a wooden cylinder, according to its position by the turning of the cylinder. Second method:—A flexible wire is wound from a wooden to a brass cylinder, or *vice versâ;* the brass cylinder being connected with one circuit wire; the wooden cylinder carries the wire included in the circuit. Third method:—A wire is bent backwards and forwards on the surface of a fixed wooden cylinder, parallel to its axis; the amount in the circuit depending on the position of a spring, moving, from the centre, over studs terminating each double length of wire. 3rd. "A new method of constructing electro-magnets." Insulated copper ribbon is coiled in concentric grooves cut in the face of a soft iron disc, the grooves communicating by a notch. 4th. "New means of arranging the parts of an electro-magnetic engine." Horseshoe electro-magnets are fixed in the circumference of a circle, and a soft iron ring or armature rolls over them; the armature being excentric to the magnets, gives motion to an axis fixed in their centre. Another method:—The axis of a soft iron disc or armature is inclined "to the axis of the circle of the fixed electro-magnets," and works in sockets in the driving shaft at one end, and in a crank attached to the driving shaft at the other end; the axis of the disc "describes the surface of a "cone," and the disc, by rolling over the fixed electro-magnets, gives motion to the driving shaft. The following are modifications of the application of the principle of giving a rolling motion to an armature in an electro-magnetic engine:—The armature may roll over other lines besides a circle; a reciprocating motion may be given by the armatures rolling over the electro-magnets in a straight line backwards and forwards; either electro-magnets or armatures may move; both may be electro-magnets; and separate armatures may be used. 5th. "A new mode of combining the parts of an electro-magnetic engine." The driving shaft carries horseshoe permanent magnets (their poles radiating outwards and disposed alternately) in front of a fixed circular frame supporting electro-magnets at right angles to the permanent magnets, and with their similar poles opposed. By interrupting and reversing the current by means of an inlaid disc alternately connected, called a "rheotrope," motion of the driving shaft is obtained. The coils of the electro-magnets form a continuous single circuit. The following modifications are stated:—Coils may be used instead of electro-magnets; the electro-magnets or coils may be lengthened in the radial direction; electro-magnets may be used instead of permanent magnets; the electric current may pass through all the coils simultaneously; magnetic bars may be used, with similar poles outwards, instead of horseshoe magnets, the coils being then wound in the same direction, and the current merely being interrupted; also any number of circles of magnetic bars and electro-magnets or coils may be used on the same axis; by this means both sides of the magnets and coils (except the exterior ones) are used. 6th. Releasing the "detent" of a clockwork by means of an electro-magnet, thus causing a hammer to impress characters upon a surface. The application of this invention "to the electro-magnetic

telegraph" described in the specification of patent No. 8345, is set forth. "Two independent movements" are employed; one to bring "any required stamp to the proper position," (similar to the mechanism described in No. 8345, except that "steel punches," at the extremity of separate radiating springs, are substituted for the "paper disc"); another to move "the cylinder so that the type may be opposite to a fresh place," and to cause "the hammer to strike upon it when placed there." The detent has a piece of soft iron at its upper end, and is released from "the quickest wheel" "of the train" by the electro-magnet when the current passes, but has a "projection bearing against" a "slower wheel," that prevents the detent returning until its revolution. A "pin" is fixed on the slower wheel, which, by striking against a ratchet wheel and lever, puts in motion respectively the cylinder and the hammer to strike the punch. The cylinder may be moved helically by being rotated on an axis moving on a fixed screw; or a platform moved by a rack and pinion may be used. Alternate layers of white and blackened paper are employed to receive the impressions of the punch. 7th. Obtaining "any determined succession of independent and dissimilar actions," by means of a single electric circuit acting successively on electro-magnets through an inlaid disc. The application of this apparatus to telegraphic printing is set forth. By means of a spring rotating by clockwork over an ivory "disc," inlaid with metal pieces in connection with separate electro-magnets and mechanical movements, the clockwork is released, the type-wheel moved, the cylinder advanced, and the blow of the hammer struck; the spring then comes again to its first position; one end of the circuit wire is connected with the rotating spring, the other with the remaining ends of the wires of the electro-magnets. 8th. Recording the time at which distant actions take place. A surface carrying paper, ruled to represent equal intervals of time, is made to move uniformly by clockwork; and an electro-magnet, included in the circuit, has a lever armature carrying a pencil, which is depressed, and marks the paper whenever the circuit is completed.

A.D. 1841, August 21.—No. 9053.—De Moleyns, Frederick.—"Certain improvements in the production or development of electricity, and the application of electricity for the attainment of illumination and motion," relating to:—1st. A galvanic battery, composed of a mixture of a solution of nitrate of ammonia and sulphuric acid in contact with a "platina" plate, and muriate of ammonia in contact with an unamalgamated zinc plate; a sycamore porous cell divides the fluids. 2nd. A means of generating the electric light, by constantly supplying the electrodes at their junction with "pulverized charcoal" from a tube in which the upper electrode is enclosed. The electrodes consist of two coils of platinum wire of suitable thickness, the lower one enclosing a piece of spongy platinum. The whole arrangement is enclosed in an exhausted glass globe. 3rd. Constructing an electro-magnet, by rolling "a strip of sheet iron" with insulated wires laid upon it "upon a cylindrical rod," so that upon its withdrawal the sheet iron and wires may present "a compact electro-magnet, each wire having a surface of iron on both sides;" the hollow portion of the magnet may be filled up with an iron rod. An electro-magnet is described, consisting of "soft iron hollow cylinders," properly covered with insulated wires, introduced into one another, and fastened by "a screw." The above, or any other electro-magnets, are applied to electro-motion by fixing them on the rim and spokes of "a wooden wheel," "parallel to its axis;" similar electro-magnets are fixed so that their poles "are opposed" to the poles of those on the wheel; the motion of the wheel is produced by "a change in the polarities of the fixed magnets effected by a commutator worked by the wheel."

A.D. 1841, September 8.—No. 9077.—Barratt, Oglethorpe Wakelin.—"Certain improvements in the precipitation or deposition of metals," consisting of:—1st. The application of electric currents for the purpose of depositing copper and its alloys taken into solution in the acids employed during the process of cleaning such metals." "A saturated solution of copper" is made in dilute "dipping aquefortis." The work to be cleaned is placed in this solution in connection with the wire from the negative battery plate, and plates of copper are connected with the positive battery plate. If the articles to be cleaned are required bright, "free acid" is added; but if they are required dead, "muriatic acid" is added. 2nd. A mode of electro-depositing zinc "upon other metals." The articles to be coated are placed in a solution of zinc "in diluted sulphuric acid cold" in connection with the positive battery plate, a plate of zinc being attached to the negative battery plate. If amalgamated zinc is used in the battery, the zinc plates in the depositing liquid may be slightly amalgamated, otherwise they are not amalgamated. Other solutions of zinc may be used. 3rd. Two methods of electro-coppering iron and other metals. First, the articles to be coated are connected with a zinc plate wrapped in cloth, and the whole is immersed in an acid solution of sulphate of copper. Second, a solution of sulphate or "cyanuret" of copper is made in "cyanuret of potassium" by boiling. The articles are then immersed in this solution, proper battery connections being made with them and with copper plates in the solution. Other compounds of potassium or sodium may be used. If a brass surface is desired, zinc is electro-deposited on the copper surface, and a heat of 300° Fahrenheit is applied "in a muffle." 4th. Modes of depositing platinum from its solutions "as a covering to other metals." The article is connected to a zinc plate, and the whole immersed in an acid solution of platinum. Another process is to dissolve platinum in certain proportions of muriate of soda, alum, cream of tartar, and water; this solution may be used with or without the battery. Palladium may "be employed in like manner." 5th. Electro-depositing copper from mineral waters. A porous earthenware vessel is placed in a pit containing the cupreous solution and filled with a solution of muriate of soda. Iron is then placed in the porous vessel and connected with the sheets of metal intended to receive the deposit of copper. 6th. Gilding, silvering, or platinating. The metallic sulphuret is dissolved by boiling in hydrate of potash. These solutions may be used with or without a battery. 7th. Electro-depositing alloys of metals. The sulphurets of the metals forming the alloy, in the proportions requisite to make the alloy, are dissolved in "cyanuret of potassium." An "alloyed anode" of "the proportions contained in the solution" is employed "when using a galvanic or other battery."

A.D. 1841, December 9.—No. 9167.—Talbot, William Henry Fox.—"Improvements in coating or covering metals with other metals, and in colouring metallic surfaces," consisting of:—1st. "Adding gallic acid to the metallic solution intended to be precipitated." "A clean bright plate of metal" is immersed in "any convenient solution of silver, gold, or platina," to which an alcoholic solution of gallic acid has been added. 2nd. "A method of silvering metallic surfaces." "A clean bright plate of metal," is immersed in a solution of "freshly precipitated chloride of silver in hyposulphite of soda, or any other liquid hyposulphite." In either the 1st or 2nd process, a galvanic battery may be employed "to obtain thicker coats of metal;" "brass, copper, silver, German silver, and also (though less effectually) iron and steel" may thus be coated. 3rd. "Ornamenting surfaces of brass or copper, by first gilding them partially according to some pattern, and then washing them over with a solution of chloride of platina," which "gives a dead black appearance" to the parts not gilt. 4th. "A method of colouring polished surfaces of copper by exposing them to the vapour of sulphuretted hydrogen, or of any of the liquid hydro-sulphurets, or to the vapours of sulphur, iodine, bromine, or chlorine, or by dipping the metal into liquids containing them." Effective ornamental patterns may thus be produced, and "as it is easy to render the copper nearly white" by this method, it may be employed "for obtaining metallic specula or mirrors as follows:"—An electrotype cast from a polished surface is exposed "to the action of the vapours," "until it is sufficiently whitened;" the surface thus obtained is not liable to tarnish by exposure to the atmosphere.

How to Test Quicksilver and Detect Adulteration.—Quicksilver, after being extracted by the plain process of retorting, is seldom quite pure, and generally contains a small proportion of other metals. The eminent naturalist, Priestly, suggests a very simple method to purify mercury, by merely shaking it strongly in an iron flask, and renewing the air in the same repeatedly with a pair of bellows. By this manipulation a black powder will be formed on the surface, which can easily be separated. If no more of this dust is formed the quicksilver may be considered pure. In this state it will always give a clear sound when agitated in the flask, while an admixture of lead will make it sound dull, as if the vessel were made of potter's clay. It is often found in the market wilfully adulterated with lead, tin, and bismuth. Of lead, it can absorb or dissolve almost one-half of its weight, without losing much of its liquidity. This adulteration can easily be discovered by rubbing some of the metal on the open palm; if it soils the skin it is adulterated—if pure, it leaves no trace. Besides, if dosed with lead, it will leave a tail behind—*il fait la queue*, to use a French expression—that is, the drops, instead of being globular, will assume an elongated form, and a more or less flattened surface. Some of these observations may be, perhaps, useful to the electrician, as many complaints have latterly been heard about the impurity of the quicksilver sold for batteries, which fact is also proved by the frequent occurrence and admixture of base metal in the amalgam gold, probably in most cases by artificial means.

TELEGRAPHIC NEWS.

MAGNETIC TELEGRAPH COMPANY.—During the alterations now being made in the building, 58, Threadneedle-street, the offices of the secretary and superintendent of the above company will be at No. 54, Hercules-passage, Old Broad-street, E.C.

THE TELEGRAPH TO AMERICA.—At the general court of the Governor and Company of Adventurers of England trading into Hudson's Bay, held on the 28th ultimo, the chairman, Sir Edmund Head, observed with respect to the proposed line of telegraph through the Hudson's Bay territory—"The committee, as stated in the latter part of the report, had dispatched Dr. Rae out with an assistant, although the country between Red River and the Rocky Mountains was well known. The object was to examine and report on the best line for crossing the territory, and traversing the Rocky Mountains between Fort Edmonton and the head waters of the river Frazer. Dr. Rae's report might be expected at any moment." In reply to various questions put by shareholders, the chairman said—"The Board had offered to the Government to make a telegraph from the Red River to the Pacific, but they had not offered to make a thousand miles of railway for the benefit of Canada without being paid for it. Telegraphic communication was at present almost all in the hands of the United States."

THE OVERLAND TELEGRAPH THROUGH THE HUDSON'S BAY TERRITORY.—We see by a Vancouver paper that a letter has been received in that city from Dr. Rae, dated Fort Alexandria. The gallant explorer was then on the point of resuming his journey westward. He says:—"I came across by the Leather Pass to Tête Jaune Cache, sent my assistant back with three of the men and fourteen of the horses, bought two small Indian canoes, and not being able to get a guide, came down with three men, and ran all the rapids safely; and from Fort George sent back the Red River men, for whom five horses were left at the Tête Jaune Cache, to take them on to Edmonton, and I came on to this place in a small canoe with one man. My opinion of the route is very favourable for a telegraph. The difficulties will be falling timbers and fires, both of which may to a great extent be guarded against. I start shortly with the view of finding a nearer road to the Tête Jaune, and hope to get much information from Judge Begbie, at William's Creek."

DESTRUCTIVE FIRE AT A TELEGRAPH CABLE MANUFACTORY.—On Sunday evening the 27th ultimo, about eight o'clock, a fire broke out at the works of Messrs. J. & E. Wright, rope and patent submarine electric telegraph cable manufacturers, situate in Glenelg-road, West Ferry-road, Millwall. The premises were of great extent, and covered a large area of ground, some of the buildings being filled with intricate and costly machinery for the manufacture of rope. At the time before stated the private watchman had his attention drawn to a strong glare in one of the store-rooms, and on closer examination he found the place to be on fire. Owing to a large portion of the stock consisting of hemp and flax, the fire extended rapidly, the several store-rooms soon being in flames. It then spread to the offices and manufactory, and also to a large store of pitch and tar, in all about 500 barrels. The Millwall Volunteer Fire Brigade, with Mr. Roberts, their chief, promptly attended, and exerted themselves very creditably, but the flames, fanned by the wind, took possession of the rope-ground, which is of considerable length, and about 280 feet of it was destroyed. The fire also extended to the engine-house, and burnt the roof off, and also the roof of the tarring-house. By this time the London Brigade had arrived, and succeeded in extinguishing the flames. Although a large part of the property is consumed, yet a very considerable portion of the works has escaped destruction, so that the business of the firm will not suffer. The extent of damage is estimated at £10,000. The property is insured in the Royal, Commercial, and other offices.

NEW ZEALAND TELEGRAPHS.—Steps are now being taken by the general Government to lay down the electric telegraph from Auckland to Dunedin, a distance of about 1,000 miles; although possibly the native war may interfere for some time with its construction in the Northern Island; that portion running through the South Island, from Nelson viâ Picton, Christchurch, &c., to Dunedin, will, it is hoped, be in active operation within a few months, contracts for poles, &c., having been already accepted. Whether the rocky deep bed of Cook's Straits will be suitable for a submarine cable remains to be tested by survey and experiment. The distance from shore to shore is not very great, being in one place less than 25 miles. It will doubtless be some time before this portion of the work will be undertaken. The Morse instrument will be used. The work of connecting Invercargill with Dunedin by means of the electric telegraph is so far advanced that messages may be expected to be transmitted in the course of a few weeks. Nearly the whole of the posts are fixed, and the chief work to be done is to suspend the wires. What the effect of this interprovincial telegraph will be upon the future of Southland is a very tempting subject for speculation. It will certainly lend vast additional importance to Bluff's Harbour, which must, under any circumstances, be the telegraphic terminus of New Zealand. On the opening of this line both Otago and Canterbury will get their first English and intercolonial news viâ Invercargill.

OVERLAND ROUTE TO BRITISH COLUMBIA.—Dr. Rae was at the dinner of the Victoria Agricultural and Horticultural Society on the 29th September, and stated in his speech that the telegraph would be completed in about two years. The distance from Red River to Tête Jaune Cache was 1,200 miles, and by cutting a line through to William's Creek, instead of following the course of the Frazer river, the distance from that point to Victoria would be some 600 miles. He had studied the question of an overland route when the "bogus" company was established in London to carry passengers across, and he was firmly convinced that letters could be carried by it from England to Victoria in six or seven weeks, which he believed was about the present mail time. He had selected the Tête Jaune Pass as the most practicable route through the Rocky Mountains for several reasons—viz., because it was opposite the Saskatchewan river, the great inland highway, flowing through vast fertile plains; because there was abundance of fine land along the route, which would raise fine crops of wheat and barley; and because there was no land to clear. At Edmonton, 300 miles from Tête Jaune, he had seen 1,000 bushels of fine wheat grown, and a gentleman who had resided and farmed there for ten years told him that only twice in all that time had the crops failed from frost. There was no difficulty whatever in laying the telegraph line, except from bush and prairie, and these might be easily prevented by the usual precautions.

MISCELLANEA.

HOW THE WEATHER IS PREDICTED IN AMERICA.—Professor Henry at the Scientific Association, gave an account of the method pursued each day at the Smithsonian Institute. They have a map of the United States hung on a board, with pins stuck through at the points where the observers of the Institute are stationed. The Institute has daily reports by telegraph from many of these points. Each morning an assistant hangs a coloured cord on the pins to indicate the state of the weather—black if rainy, green if snowing, brown if cloudy, and white if fair. All storms travel east, and thus they are enabled to predict with great certainty the condition of the weather twelve hours in advance.

THE ROYAL SOCIETY.—The annual meeting of the members of the Royal Society was held on the 30th November at their rooms, Burlington House, Piccadilly. The chair was taken by the President, General Edward Sabine, R.A., D.C.L., who delivered a lengthened adress, in which he adverted to the leading scientific and geographical discoveries of the past year, paying in passing a graceful compliment to the memory of the late Captain Speke, the discoverer of the source of the Nile. At the close of the address, Dr. W. A. Miller was elected treasurer for the ensuing year, and Dr. William Sharpey and Mr. George Gabriel Stokes, M.A., secretaries. A council was elected, comprising the Earl Stanhope, Dr. Thomas Watson, Professor Wheatstone, D.C.L., Colonel Sir George Everest, C.B., Dr. James Alderson, Professor James Clerk Maxwell, M.A., Professor William Pole, C.E., the Rev. Professor Robert Willes, M.A., Mr. Geo. Busk, Dr. J. D. Hooker, Professor Henry J. Stephen Smith, M.A., Dr. Henry Bence Jones, Professor Sylvester, M.A., and other gentlemen. The Royal and Copley medals were presented by the President to the gentlemen to whom they had been adjudged. The anniversary dinner was held at Willis's Rooms in the evening.

ALUMINIUM BRONZE.—The French Society for the Encouragement of National Industry has awarded its highest testimonial, a gold medal, to Messrs. Deville and Debray, for their method of preparing aluminium bronze. Its composition is nine-tenths copper and one-tenth aluminium. It is homogeneous, and can be forged, and is second only to iron in tenacity. It is lighter than common bronze or brass—the aluminium, though but a tenth of the weight being a quarter of the volume. It has a fine grain, and wears so long that its use for journal boxes has already become more economical than common bronze, and it is not liable to cut the journals. It is not sensibly changed by air or even by weak acids, and retains its colour and brightness so well that it is deemed likely to be much used for carriage and saddle trimmings, and for cooking vessels, and even for table use instead of silver. Some trials indicate that it may also prove superior to common bronze for the manufacture of philosophical instruments. It is said to be impossible to separate the two metals when combined in these proportions.

ORNAMENTAL USES OF MICA.—The application of mica to ornamental purposes is extensively practised in Paris. When thus employed it is first cut to the desired thickness, then coated with a thin layer of fresh isinglass diluted in water, and the gold or other surface applied, after which it is allowed to dry. The sheet of mica can be easily rendered adherent to almost any article by glueing. The artisan then takes a pattern of copper, with a design cut on it, and places it on the reverse side of the mica, and with a small brush removes any superfluous parts; the required design thus remaining on the parts which have not been brushed. He then applies the colours either one or more times as may be necessary, and afterwards coats the whole with a solution of liquid glue diluted in spirits of wine, which is applied for the purpose of rendering the mica pliable. When this is effected, the mica with the design upon it is applied to the frame of the other object and fastened with glue. The junction of several pieces of mica is made imperceptible by first glueing them together with Venetian glue, and then applying a hot iron to the parts where the mica is joined together, the parts being thus completely united. From its unalterable nature, mica preserves the gilding, silvering, or colouring from deterioration, and from its diaphenity the articles so treated will preserve all their brilliancy. They are further preserved in a state of perfect cleanliness, as anything that soils them may at once be removed by washing. Mica is extensively used in the manufacture of tablet indicators for domestic and commercial telegraphs, so successfully employed by Bréguet, Grenet, and others in France and elsewhere.

Lenoir's Engine.—After laying for some time in abeyance, the development of M. Lenoir's invention in this country has been undertaken, it is said, and will be energetically carried on by the Reading Ironworks Company, who propose to construct the machine in four sizes, from ½-horse to 3-horse power, the price of which will vary from £55 to £125, and these amounts include the electrical apparatus connected with the machine. An annual royalty of £2 2s. to £3 3s. is charged for the use of the machine during the continuance of the patent.

Manufacture of Chlorine.—Many means have been employed for the manufacture of chlorine, including the application of the bichloride of copper and other bichlorides, but hitherto without success. Mr. de Tregomain has patented an invention which relates to improvements in the manufacture of chlorine by means of bichlorides, and also to the method of revivifying the latter. After the bichloride, which is heated to a deep red, has disengaged about half its chlorine, and has changed to a state of protochloride, he collects it, while in a state of fusion, and pours it on marble slabs, and then grinds it in a mill. The powder he obtains is introduced into a revivifying apparatus, in which he passes a current of air of sufficient amount, when the protochloride in powder, in coming in contact with the oxygen of the air, becomes changed into oxychloride or mixture of binoxide and bichloride of copper. In order to effect the revivification, he places the powdered oxychloride in stoneware vessels, containing hydrochloric acid at 23° Beaume, in the proportion of about 1 cwt. of dry oxychloride to 100 lbs. of acid. The matters are then heated, cooled, and crystallized, and the mother water drawn off, the crystals being dried and distilled over again.

Strange, if True.—A correspondent of the *Morning Star*, writing from Edinburgh on the 25th ultimo, says, "Yesterday, taking up one of the local newspapers for the purpose of perusing the telegraphic summary of Mr. Cobden's speech at Rochdale, I was immediately launched upon a sea of bewilderment. As I read the sense was continually tumbling over precipices and getting lost. Every now and then a sentence performed the feat of jumping down its own throat. Here an idea would duck under like a sea bird, and appear again in the most unexpected place, and in the strangest company. In the most mysterious manner one thing melted into another like the scenes in dissolving views. What could it mean? Was Mr. Cobden mad or was I? Was Mr. Cobden drunk when he spoke? Was I drunk when I read? Was the telegraph drunk when it reported? There was a strong spirit of lunacy in the matter without question, and turning to an editorial note the mystery was solved at last. The editor lacking time and patience to comb and dress the dishevelled telegraphic summary into sense and coherence, and wishing also to let the public know in what sort of way the work is done at the telegraph office here, had printed the communication as it had arrived, inexplicable punctuation and all." The correspondent of the *Star* enquires whether Mr. Cobden, himself, or the telegraph, was under "the influence?" From the foregoing statement we incline to the opinion that the telegram was received by the editor in question in proper order, that by some means the pages became transposed in the hands of the gentleman of the press who found himself "incapable" of combing and dressing, or giving coherence to anything. The explanatory (?) foot-note referred to must have been added by some commisserating subordinate in the newspaper office—the "devil" mayhap.

PATENTS.

APPLICATION FOR LETTERS PATENT.

2950. T. Knowles, improvements in switches or points for railways.
2935. R. Wheble, improvements in the means of and apparatus for communicating between passengers, guards, and drivers of railway trains.
2941. P. E. Gaiffe and E. Zolinicki, an engraving apparatus, called "Electro-graphique."

NOTICES TO PROCEED.

1840. P. Le Boulengé, an electro-balistic chronographe.
1906. E. Tattersall, improvements in effecting communications in railways between passengers and guard.
2486. C. H. Collette, improvements in magneto-electric machines.—A communication.

NOTICE OF APPLICATION FOR THE CONFIRMATION OF A PATENT.

2800. W. A. Shepard, for improvements in preparing and treating gutta-percha and india-rubber.

PATENTS ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF THEIR PRODUCTION FOR CERTIFICATE.

3015. E. Tyer, improvements in electric telegraphs.—November 29th, 1861.
2997. H. Wilde, improvements in magneto-electric telegraphs and in apparatus connected therewith.—November 28th, 1861.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2607. A. Reynolds, improved mode of manufacturing sulphuric acid.
2675. A. Parkes, improvements in manufacturing compounds of gun cotton, and other vegetable substances similarly prepared, also in the preparation of castor and cotton oils and gum ballata, to be used with or separate from such com[illegible]ds.
2813. E. Richardson, improvements in means and apparatus for producing or effecting fog-signals.
2857. R. Holiday, improvements in the mode of locking or securing the levers used to work railway signals and points.

PATENT SEALED.

1405. W. H. Preece, improved domestic telegraphic apparatus.

PATENTS WHICH HAVE BECOME VOID.

2850. W. Clark, the application of electricity in refining cast-iron for the purpose of converting it into wrought-iron or steel, with or without the addition of other agents.—A communication.
2866. J. Macintosh, an improvement in preparing telegraphic wire which is coated with gutta-percha, in order to render it more capable of resisting heat, and in laying down telegraph wires in the sea.

PRICES CURRENT OF INSULATING MATERIAL.

Gutta Percha, as imported.

Genuine, fine and good	1/9 to 2/	per lb.

India Rubber.

Para, first quality	1/7 to 1/8	"
second "	1/4 to 1/5	"
third Negro-head	1/1 to 1/2	"
Java and Penang	1/2 to 1/4	"

TO CORRESPONDENTS.

J. H. S.—We will send you the information required per post.

G. Whyte.—The cores of soft iron are wound with half a mile of silk-covered wire.

Henry Eglinton.—The best synchronous printing telegraph now in use is Hughes's, which is employed with great success on several lines in France.

A Subscriber.—Messrs. Rose & Co., of 66, Upper Thames-street, supply the article at £31 per ton.

Telegrapher.—Professor Daniell discovered the constant battery which bears his name in the year 1837.

Edward Butler.—Besides Culley's "Handbook of Practical Telegraphy," we can recommend Mr. Prescott's "History of the Electric Telegraph."

W. E.—Harrison Gray Dyar erected an experimental line of telegraph at Long Island, U. S., in 1827 or 1828. On this line he employed frictional electricity to make a mark on paper prepared with saline solutions.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. Smith & Co., Strand; J. Onwhyn, Catherine-street, Strand; Messrs. Dawson & Co., Cannon-street E.C.; Messrs. Kent & Co., Paternoster-row, London. Messrs. Heywood & Co. Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4s. 4d. | Half-yearly, 8s. 8d. | Yearly, 17s. 4d.

TO ADVERTISERS.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electric apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before Seven o'Clock on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.
Whole page	4 4 0	Quarter page	[illegible]
Half ditto	2 10 0	Four lines and under (single col.)	[illegible]

Single Advertisements from the country must be accompanied with [illegible] payment.

ON RAILWAY ELECTRIC SIGNALLING.

BY W. H. PREECE, ASSOC. INST. C.E.

(*Continued from page* 267.)

Now the last, and, perhaps, the most important, requirement demanded of us is, that any derangement of the apparatus, or the accidental delivery of a false signal, either by the man himself or by the mechanical interruptions to which the wires are liable, shall at once indicate danger and produce safety. I have previously observed that it is impossible to make the "all clear" signal at one station without the consent and action of the man at the other station; and, moreover, I have shown that this signal cannot be complete until it has been acknowledged by the man at the distant station, and not then unless the instruments have acted correctly. It therefore follows that the derangement of the apparatus, or the accidental delivery of a false signal, at once attracts attention, and indicates danger.

The accidents to which electric signals are liable require some consideration. They are numerous, and depend upon several natural and artificial causes.

It will be observed in carrying out this system of signalling, that a distinct and separate wire is employed for each operation. Each action is performed totally independent of the other. The advantages of this are numerous. Each instrument having its distinct duty to be performed, should anything break or become disordered it can be easily replaced without disarranging or removing the whole apparatus. When any defect or accident, such as the breaking of a spring or the loosening of a screw, occurs, its position or cause is at once evident, and within the power of any intelligent signalman to rectify. If either wire or any part of the apparatus is placed *hors de combat*, temporary communication and protection can be maintained by some preconcerted system upon the other wires. Should the bell-wire fail, attention can be obtained and communication conducted by means of the semaphores. Should one or both semaphores fail, signalling can be temporarily carried on by means of the bell-wire. The use of three wires also enables us to accomplish that perfect system of repetition which is so conducive to safety and productive of confidence, and to maintain that permanent system of signalling which signifies to us at once any failure in the mechanism or accident to the wire. Where a single line exists, it is only necessary to have two wires—one for the bell circuit and one for the line; and the signalling can be conducted as effectively as for two lines with three wires.

Now, it is perfectly practicable to conduct a system of signalling upon the principles I have enunciated with one wire —and it is so done on the Charing Cross Extension of the South Eastern Company—but the adoption of one wire not only necessitates the abandonment of the complete check afforded by the repeating system, but it renders the system liable to all the dangers arising from a flood of accidental and natural causes.

When three wires are employed, the all clear signal is maintained by a constant and permanent flow of electricity—the result is, that if this current be interrupted or stopped by any cause, the arm will at once fly up, and the danger signal be exhibited. When one wire only is employed, the necessary signals are produced by momentary currents of electricity, and the permanence of the signal is maintained by local magnetism or gravity—the result is, that no derangement of the apparatus or wire is reported, and the instrument may continue to show safety when danger really exists.

The use of momentary currents necessarily leaves what is termed an open circuit, and leaves the instruments peculiarly liable to all the disturbances of atmospheric electricity. A flash of lightning might directly enter the wire, and derange both instruments, but when three wires and permanent currents are employed, the lightning would at once be conducted quietly to the earth without passing through the semaphore. But the most dangerous action of atmospheric electricity is the inductive action of a cloud charged with electricity, which might be passing even at the distance of several miles. This inductive effect invariably takes the form of a momentary current, as though it emanated from a powerful battery. It is singularly destructive to the correct working of the needles of the ordinary speaking telegraph. It sometimes completely demagnetizes the needles, and at other times reverses their magnetism so that they give totally opposite indications to that which they are intended to record. It is for this reason that I consider the ordinary needles inadmissible into railway signals, because a flash of lightning may make them say "line clear," when they should say "line blocked:" they indicate safety when there may be danger. Now, with three wires and persistent currents such inductive effects are harmless, but with single wires and momentary currents they are dangerous: they might give false signals. The arm might be lowered when it should continue raised, and the absence of any repeater or check would endanger the line.

Another natural phenomenon—that commonly termed "deflections" or "earth currents"—seriously affects circuits worked by momentary currents. At certain times and seasons immense masses of electricity pass through the crust of the earth, traversing the telegraph circuits in their course, and causing great annoyance and trouble to the speaking telegraphs. In instruments worked by permanent currents they can never produce any effect, because on short circuits they never equal in force the ordinary working currents; but instruments worked by momentary currents require to be much more delicately set, and therefore are liable to be actuated by earth currents, producing thereby false signals and consequent danger.

There are also interruptions arising from accidental and artificial causes. The wires may be brought into temporary contact by the wind, or, as they frequently are, by the long levers of the platelayers. Cases have been known where birds alighting upon the wires have produced similar effects. The wires may simply touch each other for an instant, but it would be quite sufficient to draw a current from one wire, and produce what is called a *contact*. These occasional contacts—"intermittent," as they are technically called—produce false signals on instruments worked by momentary currents, while those actuated by continuous currents would remain unharmed.*

* An accident which occurred on the London, Brighton, and South Coast Railway, near the Victoria Station, on October 16th, 1860, was undoubtedly due to this cause. Captain Tyler said, in his Report to the Board of Trade:—"There is no question in this case of any irregularity in the working of the instruments, or of the needle having been pushed over accidentally at the Victoria Junction, because the statements of Bucknell and Agent are to the effect that they both saw the needle go over, and both heard the bell ring at the same time, though they could not be sure as to whether it rang three times or not."

The use of momentary currents also necessitates the use of two keys or buttons to send the opposite currents instead of reversing them in the instrument itself, so that the signalman has sometimes to push one button and sometimes the other; and in some systems he has to do this to make the same signal. The same key that rings the bell makes the signal. This is a serious defect, as in the hurry of the moment the signalman may press the wrong key—an accident that has frequently occurred.

But a contact may be "full" or continuous. The wires may be blown together; a wire may be broken by frost, rust, or force, and fall over the others; an insulator or its binding may break; and drop one wire on to another; workmen may accidentally twist the wires together; poles, signal-posts, trees, &c., may be blown down by the wind, and bring all the wires together; wires may be wilfully twisted by evil-disposed persons; a train may run off the line, and knock down posts and wires; and numerous other causes may bring the wires together. Now, it is essential when such accidents occur that either the instruments be unaffected, or else that they at once give evidence of the accident, or exhibit the danger-signal, and thereby secure safety. Instruments worked by momentary currents upon one wire under such circumstances give false signals, and indicate false security; but those worked by permanent currents at once show danger. Whatever happens to the wire, whether it be broken or in contact with another wire, or touching the earth, will at once cause the semaphore or disc to indicate the danger signal, and secure safety. It is not so with instruments worked by momentary currents, and therefore I contend that systems based upon such a principle, and dependent upon one wire and momentary currents for their action, are fundamentally wrong and dangerous in practice. What is wrong in principle cannot be right in practice, and though we have not yet had any serious disaster from the failure of one of these single-wire signalling systems, the day must come when experience will show their utter incapacity and complete insufficiency to secure absolute safety.

There are several arguments adduced against the use of three wires and persistent currents. The first is their cost and annual maintenance expenditure; but who would weigh the comparative cost where absolute security is attained as against probable danger? And what is the difference in cost? About £15 per mile, and £1 per mile per annum! for three wires as against one. Again, it is urged that batteries get weaker and weaker when employed for persistent currents, until failure of signals takes place. Undoubtedly; so does a lamp burn out if not replenished with oil; so will a fire go out if not fed with coal; but while the duration of a fire can be counted in minutes, that of a lamp in hours, a battery remains in action for months. A battery requires occasional attention to maintain it in order, as does every other convenience where materials are consumed and power generated. But any diminution in the strength of the battery is immediately exhibited on the semaphore by the sluggishness with which the arm falls to "all clear." Men are detailed especially for this duty, and whenever the action of the semaphore becomes sluggish their attention is at once called to it by the signalman. It is also stated that in the event of a wire fracturing it would foul the others, and by thus dividing the current record a false signal. This objection may be true for needle instruments, but it cannot apply to the semaphores, for such an occurrence has the instant effect of raising the danger signal and securing safety, as I have previously explained.

I have now completed the discussion of the various points desiderated as necessary for the security of a system of railway electric signalling. I have shown how a perfect means of communication can be established between two stations for the announcement of the approach and departure of trains; how an unmistakeable and unalterable "danger" and "all clear" signal can be established at a distant station; how this can be effected with absolute security and perfect confidence, and how every accident, either of carelessness, absence, or accident, can only provoke security and avoid accident. Moreover, I do not theorise, but explain what is fully carried out in practice, and what is easily observable by anyone who chooses to examine the system at work. It now only remains for me to explain the practical working of the system, and the different localities of a line where electric signalling is serviceable.

Having described the various parts of the apparatus and their connexion as a whole, it now remains for me to explain the various railway purposes to which it is applicable. And, first, as regards the

BLOCK SYSTEM.

It is scarcely necessary to enlarge upon this particular point, because it has been borne in view and discussed throughout the preceding pages. The instructions which are given to signalmen who work this system of signalling are as follows:—

1. No train or engine is to be allowed to pass your box unless the electric signal for the section into which it is about to proceed stands at ALL CLEAR.

2. When a train has entered the section of line which you have protected (under Rule 4), you will signal to the next station, two beats on the bell *twice*, to signify "Train coming; be ready."

3. On the approach or arrival of the train or engine at your box, you will, provided the electric signal stands at ALL CLEAR, at once signal it on the bell to the next station in advance, thus:—

If a passenger train .. by 2 beats.
" goods train ...... " 3 "
" special or engine . " 4 "

4. This signal will be acknowledged by the corresponding station, by throwing his switch-handle over to "ON," thereby placing the electric signal at your station at DANGER, and protecting the line from any train following that already in the section.

5. You will acknowledge this signal by returning one beat of the bell.

6. On the arrival of the $\left\{\begin{matrix}\text{Down}\\ \text{Up}\end{matrix}\right\}$ train at $\left\{\begin{matrix}\text{A}\\ \ \end{matrix}\right\}$, the signalman at that station will pull his switch-handle over to OFF, thereby removing your danger signal, intimating the arrival of the train and clearing the line.

7. This you will acknowledge by one beat on the bell.

8. In case any obstruction exists upon the line to necessitate its being blocked, give five sharp beats on the bell (which must be repeated), and raise the electric signal to *Danger*, which must be maintained as long as the obstruction lasts.

9. No signal is to be considered complete until it has been acknowledged.

1. The first rule is very widely departed from on most lines which adopt electric signalling. On the London and North Western Railway any engine or train arriving before the line has been cleared is *ordered* to be stopped, and the driver and guard told by the policeman on duty that the line is blocked, according to the instruction of the instrument. It is then allowed to proceed with caution. Two, three, and sometimes even four trains, are allowed to be on the same section of line at the same time. The system of signalling thus becomes simply a medium of warning and caution, and by no means an element of safety from collision, as the Reports of the Government Inspectors to the Board of Trade abundantly prove.

The Great Northern Railway adopt a somewhat similar plan, and until recently the London and Brighton Railway Company did the same; but three successive accidents in one month, all arising from the absence or neglect of the pure block system upon their main line, altered their preconceived opinions, and showed them the necessity of the block system. There can be no absolute safety unless the block be made absolute. If the distance between the signalling stations be too great to carry it out without excessive delay, they should be brought nearer together. If they cannot be brought nearer, then there is a decided necessity of a third set of rails.

2. It is found extremely convenient in practice to know that a train is approaching. The warning signal is produced by giving two beats succeeding each other after a slight interval, to distinguish the first two from the second two, and not

confuse it with No. 4 signal on the bell code. It enables a station master to cease all shunting; it calls the attention of the signalmen to their signals and points; it compels them to attend to their duties, and it prevents, what is one of the great advantages of the block system, the unnecessary exhibition of the danger signal.

3. When the train is a fast passing train, it is signalled on its approach; if a stopping train, on its arrival; or if the signal boxes be very near to each other, trains can invariably be signalled on their approach. These are matters of detail which cannot well be embodied in general instructions, and are generally given verbally or in writing, according to the peculiarities of the locality and traffic.

I have previously shown how this code can be varied to suit the different requirements of the line upon which the system is established, and how the down are distinguished from the up trains. This signal, "train in," is not given unless the signal shows "all clear," because the previous signal, No. 2, has warned the further station of the approach of a train, and he would have cleared the line if it were clear. If it is maintained an unnecessary time, it is usual to inquire the reason on the speaking telegraph, if such a telegraph exist; but if there should be no telegraph, a signal is used on the bell to express impatience, or to inquire why the signal is maintained. (No. 7 Bell Code.) If the signal is still to be maintained, the obstruction signal (5) would be given. If the signal cannot be lowered, nor the all clear signal given on the bell, from any accident to the wires or apparatus, then the train would proceed under the General Regulations. The "all clear" signal on the bell is given by three beats, given twice and repeated. This is not introduced into the instructions, because it is only used when the semaphores break down. A code of instructions for the bell is sometimes made, for the special service of the different sections and branches of a line.

4. We thus see that by (2), the approach of a train is announced, and by (3), its actual departure notified. The signalman who receives these signals, and who has the protection of the section of line over which the train is running, under his charge, by Rule 4, raises the danger signal at the station which the train has just left, to protect the line from any following train. The out-door signals always follow the electric, and are similarly placed at danger. This signal is maintained until the train has passed clear of that section.

5. The danger signal is acknowledged and repeated in such a manner that no mistake is possible. The means of accomplishing this have been so fully detailed that no more need be said about it. Its use is too evident to need remark.

6. The danger signal is maintained until the train arrives at the station towards which it is proceeding. Now the question is this,—should the signal be lowered when the train has arrived within the protection of the distant signals? when it is protected by the station standard or fixed signal? or when it has left the station? Upon the plea of security, the latter plan is undoubtedly the safest; upon the score of delay, the first is the most advantageous; but this rule must be made to suit the particular traffic of the line upon which the system is worked. I consider that every station should be supplied with a "stop" signal, independent of the station standard signal, whose indications refer to the line beyond the station, and whose signals are governed by, and should exactly correspond with, the electric signals. This signal would therefore be practically a distant signal wrought from the other station. Every train would come within the protection of the station signals, and would wait at this signal to receive instructions to proceed. Such a signal is, however, rarely used, and the necessary instructions to proceed are given by flag or hand.

I would never clear the line until the train, if a stopping train, is well under the protection of the station signals; and, if a passing train, until it has completely passed the signal box—a practice which, though general, is by no means universal. On the London and North Western line it is ruled that when the signalman observes from the appearance of the passing train that it is going slowly, or likely to fail, the block must be maintained until time has been allowed for the slow train to make some progress over the next section.

The signalman may also observe something wrong with the train,—the tail lamps off, coupling-chains unhooked, tyres loose, a carriage on fire, excited passengers unable to attract attention, &c. He would then give the attention signal (No. 7 Bell Code), and maintain the block until he was satisfied that the line was clear, or until he had ascertained through the station master, by means of the telegraph, that all was right.

There are certain large stations where shunting is always going on, and where the fixed signals are nearly always at danger. It would be impossible in such cases to adhere strictly to these rules without incurring excessive delay. Now, such stations should invariably be protected at their two extremities with signalling boxes and fixed signals, and that as soon as a train comes within the protection of these signals the line should be cleared. The points, crossings, and shunting operations, between the two boxes would all be regulated by hand and station signals. The electric signals would only protect the line beyond the electric signal boxes. Delays are thus avoided. Trains can run up to the signal boxes at the extremities of the station, while in the meantime, from the warning that has been given of the approach of the train, the station yard can be cleared, and the train admitted or passed on on its proper rails.

7. The clearing of the line is also acknowledged and faithfully reported on the repeater.

8. When any obstruction exists upon the line beyond the protection of the fixed signals, from an accident to the train or other cause, this signal is given; and when any shunting occurs which cannot be fully protected by the fixed signals it is also used. It is a very useful signal, and is always accompanied by the raising of the danger signal. When this signal is received, the out-door signals are immediately raised to danger, and nothing is allowed to pass until the line is cleared.

These rules, if fully carried out, cannot fail to ensure safety from collision; and they are believed, if rigidly obeyed, to be sufficient to carry out the block system in its entirety.

The Government Inspectors invariably recommend that a speaking telegraph should accompany every electric signalling system, to fall back upon in cases of failure, misconception, or confusion. The necessity of a telegraph is therefore based upon the assumption of the fallibility of the signalling apparatus. But my experience proves that ordinary telegraphs are far more liable to disorder than signalling apparatus; and to erect an uncertain agent for the protection of a comparatively certain one is unsound philosophy. Moreover, the presence of a telegraph tends to reduce the attention of the signalman from his own instrument. When he knows that he has a telegraph to fall back upon, he is not so likely to regard the maintenance and true working of his own apparatus. The Bell Code is constructed to meet every possible emergency that may arise in the ordinary operations of signalling; and if anything unusual or extraordinary should occur, he has but to consult the station master, who has the control of the general telegraph, without which no line should be worked.

In all the annals of railway accidents which I have examined, I can only find one instance* where a speaking telegraph would have been serviceable in rectifying a mistake and avoiding an accident, and this arose from an inefficient system; but the records of accidents arising from the failure or misconception

* *Vide* Capt. Tyler "on a collision at the Commercial Dock Station of the South Eastern Railway Company, Dec. 15th, 1860." Reports, 1861, p. 130.

of the electric telegraph are too numerous to require recapitulation. I need only refer to the lamentable accident at Clayton Tunnel, on the Brighton Railway, to instance the danger of depending upon a speaking telegraph in moments of confusion.

The Government Inspectors also require the careful entry in proper Record Books of the times of signalling and passing of all trains. This is doubtless a very effective check upon the proper discharge of his duties by the signalman, and a most valuable witness in his favour, when properly maintained, in all cases of accident. Captain Tyler says,* "A man is obviously less likely to commit an irregularity of any sort in duties of this description when he is himself compelled to make a permanent record of it, liable at any time to be brought against him, open to observation on periodical or irregular inspections, and checked by other records made by responsible officers within a short distance, and perhaps on both sides of him." Record books should invariably accompany electric signalling. In the Appendix will be found the form of Record Book adopted on the South Western Railway.

(*To be continued.*)

PNEUMATIC DISPATCH AND TELEGRAPHY.

We extract the following from the *Manchester Examiner and Times* of the 6th instant:—

Yesterday the principle of pneumatic dispatch—propulsion by atmospheric pressure through a tube in which a vacuum has been created—was put to practical commercial use in this city, to facilitate telegraphic communication. Owing to the increase of their business in Manchester, the Electric and International Telegraph Company have lately taken extensive premises in York-street, and opened a central station there. In order to facilitate the rapid dispatch of messages from the branch offices at Ducie-buildings (Royal Exchange), and No. 1, Mosley-street, it has been deemed advisable to connect these offices with the central station by means of the pneumatic system, the same as is adopted by the company in London and Liverpool. Between the branch offices above-mentioned and the central station leaden pipes, with an inside diameter of $1\frac{1}{2}$ inches, have been laid down under the streets. The leaden pipes are made perfectly air-tight, and are enclosed in 2-inch iron pipes to protect them from being damaged. At the central station there is fixed in the basement a small high-pressure beam engine, and connected with it a double-action air pump, 17 inches in diameter and 15 inches stroke. This pump is continually at work exhausting the air from a cylinder 8 feet long and 4 feet in diameter, which is styled the vacuum cylinder. The pipes which pass under the streets from the branch offices are terminated in the instrument room on the top floor of the building, and the pipes from the vacuum cylinder are also carried to the same place, and they can be put in connection by simply opening a valve. The carriers which travel through the pipes are made of gutta-percha covered with felt. They are about 5 inches long, and of a diameter nearly equal to that of the pipe. They are hollow inside for the purpose of containing the messages. Electric bells are employed to give the necessary signals for the working of the pipes. When the officials at the Ducie-buildings office wish to send a "carrier," they place one in the mouth of the pipe, and signal the central station by ringing its bell. The clerk in attendance at the latter place, by moving a small lever, puts the pipe in communication with the vacuum cylinder. The air in the pipe then rushes into the vacuum cylinder, and the "carrier," having the ordinary atmospheric pressure behind it, is propelled through at a speed of from 35 to 40 miles an hour. On the arrival of the "carrier" at the central station it strikes against a spring buffer, which, by a simple, self-acting contrivance, cuts off the communication between the pipe and the vacuum cylinder, and the "carrier" falls from the valve on to a counter prepared to receive it. To send a "carrier" from the Mosley-street office, the action is precisely the same. By using a second chamber, and compressing air into it, a force is obtained for blowing the "carriers" from the central station to the branch branch offices, so that the pipes can be made available for carrying in both directions. The great advantage of this new system is, that it enables the Electric Telegraph Company to cope with the increasing traffic, to perform the service more expeditiously and more cheaply, and also to avoid the liability to make errors consequent upon the transmission between the branch and the central stations by the usual means of telegraphing. Mosley-street to central office, 325 yards. Ducie-buildings to central office, 501 yards. The branch office in Mosley-street is about 320 yards from the central office, and the distance of the Ducie-buildings branch office is 510 yards. The time occupied by a "carrier" in traversing the shorter distance is 22 seconds. Time in travelling from Ducie-buildings to central office, 30 seconds; from Mosley-street to central office, 10 seconds. This mode of transmitting messages has been in operation in London several years. The central office in Moorgate-street is connected by pipes with nearly a dozen of the principal branch offices in different parts of the city, which are thus placed in almost instantaneous communication with the instrument room. Thus, a message for any part of the country, or for the continent, may be in process of transmission to its destination before it could be received at the central office, when every word had to be sent by the wire. A popular explanation of the principle of pneumatic dispatch was recently given in an account of the experimental railway at the Crystal Palace. It will also be remembered that the principle has been applied by the General Post-office in the transmission of mails between Euston-square and St. Martin's-le-Grand. There can be little doubt but that when the simplicity of the system becomes known it will be extensively adopted. Meanwhile, the public are indebted to the Electric Telegraph Company for proving its utility, and availing themselves of it wherever the amount of their business will warrant its application.

ON THE ELEMENTARY RELATIONS BETWEEN ELECTRICAL MEASUREMENTS.*

BY PROFESSOR J. CLERK MAXWELL AND MR. FLEEMING JENKIN.

I.

1. *Objects of Treatise.*—The progress and extension of the electrical telegraph has made a practical knowledge of electric and magnetic phenomena necessary to a large number of persons who are more or less occupied in the construction and working of the lines, and interesting to many others who are unwilling to be ignorant of the use of the network of wires which surrounds them. The discoveries of Volta and Galvani, of Oersted, and of Faraday, are familiar in the mouths of all who talk of science, while the results of those discoveries are the foundation of branches of industry conducted by many who have perhaps never heard of those illustrious names. Between the student's mere knowledge of the history of discovery and the workman's practical familiarity with particular operations which can only be communicated to others by direct imitation, we are in want of a set of rules, or rather principles, by which the laws remembered in their abstract form can be applied to estimate the forces required to effect any given practical result.

We may be called on to construct electrical apparatus for a particular purpose. In order to know how many cells are required for the battery, and of what size they should be, we require to know the strength of current required, the electro-motive force of the cells, and the resistance of the circuit. If we know the results of previous scientific inquiry, and are acquainted with the method of adapting them to the case before us, we may discover the proper arrangement at once. If we are unable to make any estimate of what is required before constructing the apparatus, we may have to encounter numerous failures which might have been avoided if we had known how to make a proper use of existing data.

All exact knowledge is founded on the comparison of one quantity with another. In many experimental researches conducted by single individuals, the absolute values of those quantities are of no importance; but whenever many persons are to act together, it is necessary that they should have a common understanding of the measures to be employed. The object of the present treatise is to assist in attaining this common understanding as to electrical measurements.

2. *Derivation of Units from Fundamental Standards.*—Every distinct kind of quantity requires a standard of its own, and these standards might be chosen quite independently of each other, and

* This paper is appended to the report of the committee, appointed by the British Association, on Standards of Electrical Resistance.

in many cases have been so chosen; but it is possible to deduce all standards of quantity from the fundamental standards adopted for length, time, and mass; and it is of great scientific and practical importance to deduce them from these standards in a systematic manner. Thus it is easy to understand what a square foot is when we know what a linear foot is, or to find the number of cubic feet in a room from its length, breadth, and height; because the foot, the square foot, and the cubic foot are parts of the same system of units. But the pint, gallon, &c., form another set of measures of volume which has been formed without reference to the system based on length; and in order to reduce the one set of numbers to the other, we have to multiply by a troublesome fraction, difficult to remember, and therefore a fruitful source of error.

The varieties of weights and measures which formerly prevailed in this country, when different measures were adopted for different kinds of goods, may be taken as an example of the principle of unsystematized standards, while the modern French system, in which everything is derived from the elementary standards, exhibits the simplicity of the systematic arrangement.

In the opinion of the most practical and the most scientific men, a system in which every unit is derived from the primary units with decimal subdivisions is the best whenever it can be introduced. It is easily learnt; it renders calculation of all kinds simpler; it is more readily accepted by the world at large; and it bears the stamp of the authority, not of this or that legislator or man of science, but of nature.

The phenomena by which electricity is known to us are of a mechanical kind, and therefore they must be measured by mechanical units or standards. Our task is to explain how these units may be derived from the elementary ones; in other words, we shall endeavour to show how all electric phenomena may be measured in terms of time, mass, and space only, referring briefly in each case to a practical method of effecting the observation.

3. *Standard Mechanical Units.*—In this country the standard of length is one yard, but a foot is the unit popularly adopted. In France it is the ten millionth part of the distance from the pole to the equator, measured along the earth's surface, according to the calculations of Delambre, and this measure is called a metre, and is equal to 3·280899 feet, or 39·37079 inches.

The standard unit of time in all civilized countries is deduced from the time of rotation of the earth about its axis. The sidereal day, or the true period of rotation of the earth, can be ascertained with great exactness by the ordinary observations of astronomers; and the mean solar day can be deduced from this by our knowledge of the length of the year. The unit of time adopted in all physical researches is one second of mean solar time.

The standard unit of mass is in this country the avoirdupois pound, as we received it from our ancestors. The grain is one 7,000th of a pound. In the French system it is the gramme derived from the unit of length by the use of water at a standard temperature as a standard of density. One cubic centimetre of water is a gramme = 15·43235 grains = ·00220462 lbs.

A table, showing the relative value of the standard and derived units in the British and metrical system, is given in section 55

The unit of force adopted in this treatise is that force which will produce a unit of velocity in a free unit mass by acting on it during a unit of time. This unit of force is equal to the weight of the unit mass divided by g, where g is the accelerating force of gravity

$$\left.\begin{array}{l} = 32{\cdot}088\ (1 + 0{\cdot}005133 \sin^2 \lambda) \text{ in British units} \\ \text{or } = 9{\cdot}78024\ (1 + 0{\cdot}005133 \sin^2 \lambda) \text{ in metrical units} \end{array}\right\} \text{at the level of the sea,}$$

λ being the latitude of the place of observation. A unit of force still very generally adopted is the weight of the standard mass. The value of the new unit is $\frac{1}{g}$ times the old or gravitation unit.

The unit of work adopted in this treatise is the unit of force, defined as above, acting through the unit of space.

4. *Dimensions of Derived Units.*—Every measurement of which we have to speak involves as factors measurements of time, space, and mass only; but these measurements enter sometimes at one power, and sometimes at another. In passing from one set of fundamental units to another, and for other purposes, it is useful to know at what power each of these fundamental measurements enters into the derived measure.

Thus the value of a force is directly proportional to a length and a mass, but inversely proportional to the square of a time. This is expressed by saying that the *dimensions* of a force are $\frac{LM}{T^2}$; in other words, if we wish to pass from the English to the French system of measurements, the French unit of force will be to the English as $\frac{3{\cdot}28 \times 15{\cdot}43}{1}$: 1, or as 50·6 to 1; because there are 3·28 feet in a metre, and 15·43 grains in a gramme. If the minute were chosen as the unit of time, the unit of force would, in either system, be $\frac{1}{3600}$ of that founded on the second as unit.

A table of the dimensions of every unit adopted in the present treatise is given in section 55.

5. *Magnets and Magnetic Poles.*—Certain natural bodies, as the iron ore called loadstone, the earth itself, and pieces of steel after being subjected to certain treatment, are found to possess the following properties, and are called magnets.

If one of these bodies be free to turn in any direction, the presence of another will cause it to set itself in a position which is conveniently described or defined by reference to certain imaginary lines occupying a fixed position in the two bodies, and called their magnetic axes. One object of our magnetic measurements will be to determine the force which one magnet exerts upon another. It is found by experiment that the greatest manifestation of force exerted by one long thin magnet on another occurs very near the ends of the two bars, and that the two ends of any one long thin magnet possess opposite qualities. This peculiarity has caused the name of "poles" to be given to the ends of long magnets; and this conception of a magnet, as having two poles capable of exerting opposite forces joined by a bar exerting no force, is so much the most familiar that we shall not hesitate to employ it, especially as many of the properties of magnets may be correctly expressed in this way; but it must be borne in mind, in speaking of poles, that they do not really exist as points or centres of force at the ends of the bar, except in the case of long, infinitely thin, uniformly magnetized rods.

If we mark the poles of any two magnets which possess similar qualities, we find that the two marked poles repel each other, that two unmarked poles also repel each other; but that a marked and an unmarked pole attract each other. The pole which is repelled from the northern regions of the earth is called a positive pole; the other end the negative pole. The negative pole is generally marked N by British instrument-makers, and is sometimes called the north pole of the magnet, whereas it is obviously similar to the earth's south pole.

The strength of a pole is necessarily defined as proportional to the force it is capable of exerting on any other pole. Hence the force f exerted between two poles of the strengths m and m_1 must be proportional to the product $m\,m_1$. The force, f, is also found to be inversely proportional to the square of the distance, D, separating the poles, and to depend on no other quantity; hence we have, unless an absurd and useless coefficient be introduced,

$$f = \frac{m\,m_1}{D^2} \qquad (1)$$

From which equation it follows that the unit pole will be that which at unit distance repels another similar pole with unit force: f will be an attraction or a repulsion, according as the poles are of opposite or the same kinds. The dimensions of the unit magnetic pole are $\frac{L^{\frac{3}{2}} M^{\frac{1}{2}}}{T}$.

6. *Magnetic Field.*—It is clear that the presence of a magnet in some way modifies the surrounding space, since any other magnet brought into that space experiences a peculiar force. The neighbourhood of a magnet is, for convenience, called a magnetic field; and for the same reason the effect produced by a magnet is often spoken of as due to the magnetic field, instead of to the magnet itself. This mode of expression is the more proper, inasmuch as the same or a similar condition of space may be produced by the passage of electrical currents in the neighbourhood, without the presence of a magnet. Since the peculiarity of the magnetic field consists in the presence of a certain force, we may numerically express the properties of the field by measuring the strength and direction of the force, or, as it may be worded, the intensity of the field and the direction of the lines of force.

This direction at any point is the direction in which the force tends to move a free pole; and the intensity, H, of the field is necessarily defined as proportional to the force, f, with which it acts on a free pole; but this force, f, is also proportional to the strength, m, of the pole introduced into the field, and it depends on no other quantities; hence

$$f = m\,\mathrm{H}, \qquad (2)$$

and therefore the field of unit intensity will be that which acts with unit force on the unit pole.

The dimensions of H are $\frac{M^{\frac{1}{2}}}{L^{\frac{1}{2}}T}$.

The lines of force produced by a long thin bar-magnet near its poles will radiate from the poles, and the intensity of the field will be equal to the quotient of the strength of the pole divided by the square of the distance from the pole; thus the unit field will be produced at the unit distance from the unit pole. In a uniform magnetic field the lines of force, as may be demonstrated, will be parallel; such a field can only be produced by special combinations of magnets, but a small field at a great distance from any one pole will be sensibly uniform. Thus, in any room unaffected by the neighbourhood of iron or magnets, the magnetic field due to the earth will be sensibly uniform; its direction will be that assumed by the dipping-needle.

7. *Magnetic Moment.*—In reality we can never have a single pole entirely free or disconnected from its opposite pole, and it is time to pass to the consideration of the effect produced on a material bar-magnet in a magnetic field. In a uniform field two equal opposite and parallel forces act on its poles, and tend to set it with the line joining those poles in the direction of the force of the field. When the magnet is so placed that the line joining the poles is at right angles to the lines of force in the field, this tendency to turn or "couple," G, is proportional to the intensity of the field, H, the strength of the poles, m, and the distance between them, l; or

$$G = m\,l\,H. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$m\,l$, or the product of the strength of the poles into the length between them, is called the magnetic moment of the magnet; and from equation (3) it follows that, in a field of unit intensity, the couple actually experienced by any magnet in the above position measures its moment. The dimensions of the unit of magnetic moment are evidently $\frac{L^{\frac{5}{2}}M^{\frac{1}{2}}}{T}$.

8. *Intensity of Magnetization.*—The intensity of magnetization of a magnet may be measured by its magnetic moment divided by its volume.

The dimensions of the unit of magnetization are therefore $\frac{M^{\frac{1}{2}}}{L^{\frac{1}{2}}T}$, the same as in the case of intensity of field.

9. *Coefficient of Magnetic Induction.*—When certain bodies, such as soft iron, &c., are placed in the magnetic field, they become magnetized by "induction;" so that the intensity of magnetization is (except when great) nearly proportional to the intensity of the field.

In diamagnetic bodies, such as bismuth, the direction of magnetization is opposite to that of the field. In paramagnetic bodies, such as iron, nickel, &c., the direction of magnetization is the same as that of the field.

The coefficient of magnetic induction is the ratio of the intensity of magnetization to the intensity of the field, and is therefore a *numerical* quantity, positive for paramagnetic bodies, negative for diamagnetic bodies.

10. *Magnetic Potentials and Equipotential Surfaces.*—If we take a very long magnet, and, keeping one pole well out of the way, move the other pole from one point to another of the magnetic field, we shall find that the forces in the field do work on the pole, or that they act as a resistance to its motion, according as the motion is with or contrary to the force acting on the pole. If the pole moves at right angles to the force, no work is done.

The *magnetic potential* at any point in a magnetic field is measured by the work done by the magnetic forces on a unit pole during its motion from an infinite distance from the magnet producing the field to the point in question, supposing the unit pole to exercise no influence on the magnetic field in question. The idea of potential as a mathematical quantity having different values at different points of space, was brought into form by Laplace.* The name of potential, and the application to a great number of electric and magnetic investigations, were introduced by George Green, in his Essay on Electricity (Nottingham, 1828).

An equipotential surface in a magnetic field is a surface so drawn that the potential of all its points shall be equal. By drawing a series of equipotential surfaces corresponding to potentials, 1, 2, 3 . . . . . . n, we may map out any magnetic field, so as to indicate its properties.

The magnetic force at any point is perpendicular to the equipotential surface at that point, and its intensity is the reciprocal of the distance between one surface and the next at that point. The dimensions of the unit of magnetic potential are $\frac{L^{\frac{1}{2}}M^{\frac{1}{2}}}{T}$.

* Méchanique Céleste, liv. iii.

11. *Lines of Magnetic Force.*—There is another way of exploring the magnetic field, and indicating the direction and magnitude of the force at any point. The conception and application of this method in all its completeness is due to Faraday.* The full importance of this method cannot be recognised till we come to electro-magnetic phenomena (sections 22, 23, and 24).

A line, whose direction at any point always coincides with that of the force acting on the pole of a magnet at that point, is called a line of magnetic force. By drawing a sufficient number of such lines, we may indicate the *direction* of the force in every part of the magnetic field; but by drawing them according to rule, we may indicate the intensity of the force at any point as well as its direction. It has been shown,† that if in any part of their course the number of lines passing through unit of area is proportional to the intensity there, the same proportion between the number of lines in unit of area and the intensity will hold good in every part of the course of the lines.

All that we have to do, therefore, is to space out the lines in any part of their course, so that the number of lines which start from unit of area is *equal* to the number representing the intensity of the field there. The intensity at any other part of the field will then be measured by the number of lines which pass through unit of area there; each line indicates a constant and equal force.

12. *Relation between Lines of Force and Equipotential Surfaces.*—The lines of force are always perpendicular to the equipotential surfaces; and the number of lines passing through unit of area of an equipotential surface is the reciprocal of the distance between that equipotential surface and the next in order—a statement made above in slightly different language.

In a uniform field the lines of force are straight, parallel, and equidistant; and the equipotential surfaces are planes perpendicular to the lines of force, and equidistant from each other.

If one magnetic pole of strength, m, be alone in the field, its lines of force are straight lines, radiating from the pole equally in all directions; and their number is $4\pi m$. The equipotential surfaces are a series of spheres, whose centres are at the pole, and whose radii are m, $\frac{1}{2}m$, $\frac{1}{3}m$, $\frac{1}{4}m$, &c. In other magnetic arrangements these lines and surfaces are more complicated, but in all cases the calculation is simple; and in many cases the lines and surfaces can be graphically constructed without any calculation.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XVIII.

A.D. 18 1, December 21.—No. 9204.—Wright, Thomas, and Bain, Alexander.—"Improvements in applying electricity to control railway engines and carriages, to mark time, to give signals, and print intelligence at distant places," relating to:—

Controlling railway engines and carriages. "The deflection of the electric conductor, or a coil of wire," moves a dial hand, and releases a "stop," thus liberating wheelwork. A weight at the end of a lever acts on the stop disc through a rack head, pinion, ratchet wheel, and spur gearing. A stud on the lever is linked to the throttle valve lever and steam whistle, both of which are acted on when the stop is released, and the weight thus permitted to descend. "A pilot engine," with a "governor," propelled by the driving wheel axle, about a mile in advance, is used in connection with the above apparatus; the electric current from a battery on the locomotive passes through "brackets" and spring "plugs" to long conducting wires laid on the line of railway, thence through the governor rod to a coil of wire, and back to the battery through the line wires; as long as the current circulates through the coil, the "stop" prevents the clockwork from acting, but when the governor balls fall, a spring in the circuit presses against a piece of ivory on the governor rod, thus interrupting the circuit, and putting the mechanism into action.

"An electro-magnetic printing telegraph." Electro-magnets are arranged in the circumference of a circle, each having a "feeder," or armature fixed to a spindle, which is attached by means of a pin to the tail of the "type lever;" the type levers (mounted between "cocks") being all made to strike the paper and a blackened ribbon at the common centre of the magnets. There is also a central magnet that draws down the soft iron type lever heads

* Experimental Researches, vol. iii. art. 3,122 *et passim*.
† *Vide* Maxwell on Faraday's Lines of Force, Cambridge Phil. Trans., 1857.

when they get sufficiently near, and another to move the paper forwards, through both of which the current passes whenever the circuit is completed. The surface of the ribbon is rubbed over with a composition of oil, lamp-black, and spirits of turpentine; and the magnet that moves the paper forward has a "feeder" or armature connected with a lever and click working into a click wheel on the shaft of the paper roller.

A method of printing and giving signals; in which a spring barrel rotates the type wheel and brings the corresponding letter to the aperture in the dial by means of a coil acting on a ratchet wheel by pallets; a second spring barrel brings the type to the paper, and moves the paper by means of a governor (rotated by the first spring barrel, and mounted on a "friction collet"), which allows an excentric and ratchet wheel to act as soon as the coil has brought the desired type opposite the paper; for this purpose the governor lever bears against knees suitably fixed on the shaft of the excentric. The coil is only deflected when the circuit is completed.

An instrument to show whether a telegraph is indicating or printing correctly at a distant station. On the completion of the circuit, the battery current rotates a hand round a disc at the distant station, by the deflection of a coil from a permanent magnet acting on the spindle of the hand through a ratchet wheel and click movement. At certain positions of the hand, a battery at the distant station is brought into action by studs, over which an insulated metal curve on the hand passes; this battery deflects a small coil at the telegraphing station, the current being at such times insulated from the instruments, by a spring in the circuit pressing against a non-conducting portion of the ratchet wheel. At the telegraphing station a steel disc is used, with ivory studs inserted, which cut off the main circuit at each deflection of the needle. This instrument is employed to work the last-mentioned telegraphic printing apparatus.

The application of the deflection of a coil to the movement of timepieces. An electric current is sent through a coil every minute by means of a pendulum or balance wheel; every deflection of the coil moves a ratchet wheel forward one tooth by a click on the coil; this motion is communicated to the hands by the ordinary clock mechanism. Two coils working two ratchet wheels may be used instead of one in any of the above applications, one coil working at a time by the reversal of the current.

"Laying down the conducting wires for telegraphic purposes in asphalt, pitch, or any other cement," "by digging a trench," and filling it to a small depth "with the cement in a soft state. When this is hardened," the wires are laid on it, and another quantity of cement in a soft state is run in the trench, and on and over the wires.

Using "bodies of natural waters" to complete the electric circuit, by laying a single insulated wire between the given stations, having at each end a metallic brush immersed in the water.

A.D. 1842, January 15.—No. 9227,—Palmer, Edward.—"Improvements in producing printing and embossing surfaces," consisting of:—1st. "A mode of obtaining surfaces for relief printing by means of the electrotype process or by casting." A smooth plate of German silver or brass, blackened on the surface, either by means of a solution of chloride of platinum or of "hydro-sulphuret of ammonia," is coated with a composition of "the clear part of Burgundy pitch," resin, white wax, and spermacetti, and its surface whitened with finely powdered sulphate of lead; lines etched upon this surface appear dark upon a white ground. The whole plate is then electrotyped, being placed in the solution before the ground is made conducting; the ground is then plumbagoed, and the electrotype proceeded with. Or a plaster cast may be taken of the subject, from which a reverse cast for stereotyping may be had by rubbing the first with lather of soap and taking a plaster cast in the usual manner. 2nd. A mode of obtaining metallic printing surfaces with the design sunken. Drawings made upon prepared surfaces are electrotyped or cast in wax, from which electrotype or casting "as many printing copies as required can be taken." To make the prepared surface, a very thin coating of a mixture of white wax and sulphate of lead is poured over a metal plate, and a border made round it when cold; a sufficient quantity of white wax mixed with plumbago is poured on this, and the tablet is taken off the plate ready for use; the design drawn on this surface appears black upon a white ground. Or a cast from an oiled polished piece of metal or glass is taken in plaster of Paris, and the design drawn on it with a black lead pencil, then etched with an engraver's needle; while working, finely-powdered charcoal is dusted into the lines; this method is preferred. 3rd. A mode of obtaining, by the electrotype or stereotype, blocks for surface printing from engraved plates. Printer's ink, mixed with driers of Brunswick black, is spread carefully over the engraved plate, so as not to fill up the engraved lines, by means of a printer's composition roller; oxide of iron mixed with litharge, in fine powder, is sifted over this, the whole dried, and the powder brushed off. This process is repeated until a sufficient thickness is obtained, and the whole is black-leaded and electrotyped, or cast from in plaster. 4th. "Obtaining embossed surfaces" by "sinking the subject in a prepared surface of plaster of Paris" (see 2nd improvement), "and then, by obtaining a cast therefrom," producing "an embossing surface by the electrotype or by casting." If the surface is to be obtained by the electrotype, a wax mould of the plaster must be taken, but if by stereotype, a plaster mould.

A.D. 1842, June 1.—No. 9374.—Lesson, Henry Beaumont.—"Improvements in the art of depositing and manufacturing metals and metal articles by electro-galvanic agency, and in the apparatus connected therewith," consisting of:—1st. A galvanic battery, in which the trough contains two removeable frames—one resting on the bottom of the trough, and containing porous cells and partitions—the other resting on the top of the trough, and containing the metal plates. The porous cell frame is not wanted when only single fluid is used. The plates are secured to "bars," projecting inwards from the side of the frame, with screw clamps, in such a manner as to be removeable singly without disturbing the others. A voltameter is described and shown, that has great area of acting surface supported in a glass vessel from a metal cover. 2nd. Cleaning zinc and copper battery plates by electricity; by first removing the impurities by immersion in an acid or saline solution, in connection with the positive pole of a battery, and then (in regard to the copper plates only) electro-depositing copper on them. Also amalgamating zinc plates by the electro-deposition of mercury on them. 3rd. Battery exciting fluids to be used in connection with sulphuric, nitric, or muriatic acids. Ammoniacal liquor from gas works, lime liquor after use in gas purifying, alkaline sulphurets, the residuum of the "processes for making potash and soda," the sulphates of calcium, barium, and strontium, the alkalies and their carbonates, and "the acid solution of sulphate of iron" produced "in the manufacture of green copperas or sulphate of iron, in connection with any of the last-mentioned alkaline solutions or sulphurets." 4th. Adjusting or diminishing the "quantitative" or electrolytical effect of a battery, by increasing the number of pairs, there being not less than ten pairs used. 5th. Using glue, either alone or together with gums, resins, or a solution of tannin, to make elastic moulds for wax electrotype casts; and a strong solution of cyanide of silver and potassium to deposit upon the casts. To projecting parts a pin of metal is attached, which receives the rough deposit that would otherwise take place on the mould; the pin is afterwards cut off. Positive wires are led into cavities or undercut portions to cause an equable deposit, and conducting wires are inserted into wax moulds to facilitate deposition. 6th. Giving motion to the article to be deposited upon (not on its own axis) by means of a roasting jack, &c.; or the depositing solution may be agitated. 7th. Forming parabolic and other reflectors by first electro-depositing the silver or other face, and then a suitable thickness of copper; the face is then highly polished. 8th. Electro-depositing alloys. First method:—By using a solution composed of similar salts of the different metals, and as many distinct galvanic batteries as metals, all the negative poles being connected to the article to be coated, and each metal to a positive pole. Second method:—A beam, moved by any suitable power, alternates the battery connection with the metals; one or two batteries may be used. Third method:—One battery may be used, and a dissolving plate of each of the metals. Fourth method:—"Any of the non-metallic electrotytic" [electrolytic?] "fluids," described in the 11th improvement, may be used "in connection with any of the hereinbefore recited arrangements." 9th. Giving a coating of mercury by immersion to prepare metallic surfaces for electro-deposition. 10th. Arranging the articles to be coated themselves, "in series as a portion of the battery," so as to assist in generating and "maintaining the galvanic current." 11th. Electro-depositing metals "by the aid of electrolytic solutions not originally containing such metals;" proto-salts and "those that form double salts with the metal" are preferred, and the electric current must be intense enough. 12th. Manufacturing platinum and other metals from their ores by electro-deposition. The solutions named in the 11th improvement are, by preference, used. The metal may at once be deposited in the required form. 13th. Manufacturing platinum vessels, &c., by electro-depositing the metal upon a

suitable mould, which is afterwards removed; a platinum cathode is used. In electro-coating articles with platinum, they are previously plumbagoed or coppered. 14th. The application of certain compounds of the metals, not before used, to furnish an electrolytic solution for their deposition. "Sulphate of silver" is mentioned twice, and "sulphate of silver and soda," "sulphate of silver and potassa," "hypo-sulphate of silver and strontia," "racinate of silver," and "sulphoriarte of silver," are also mentioned; these are referred to in the "Memorandum of Alteration." Under this head, about 430 compounds of the metals not before used, are mentioned in the list.

A "Memorandum of Alteration" was enrolled by the Patentee, March 25, 1843, in which the sentences,—"sulphate of silver," "sulphate of silver and soda," "sulphate of silver and potassa," "hyposulphate of silver and strontia," "racinate of silver," and "sulphorinate of silver," occurring in the specification,—are altered into, "sulphite of silver," "sulphite of silver and soda," "sulphite of silver and potassa," "hyposulphite of silver and strontia," "racemate of silver," and "sulphovinate of silver," respectively.

A.D. 1842, June 4.—No. 9379.—Tuck, Edmund.—"Covering or plating with silver various metals and metallic alloys." This invention "consists in the use of either of the two carbonates of ammonia, namely, the sesquicarbonate and the bicarbonate as one of the ingredients in the mixtures or compounds employed for covering or plating with silver various metals and metallic alloys by the action of electricity." A process is described for plating "bad German silver," in which "sulphate of silver" is used in combination with "a solution of bicarbonate of ammonia" in "equivalent" proportions; for plating "on copper or on good German silver," "cyanide of silver" in "equivalent" proportions is used instead of "sulphate of silver." The inventor prefers to use a modification of "Daniell's constant battery," which is described as a suitable source of electricity for electro-plating by these solutions. The arrangement of the trough for plating, the method of cleaning the metal alloy to be plated, and the regulation of battery power to the article to be coated, is set forth.

A.D. 1842, August 1.—No. 9431.—Woolrich, John Stephen.—"Improvements in coating with metal the surface of articles formed of metal or metallic alloys." A magneto-electric machine is described and shown, consisting of a horseshoe-formed armature, revolving in front of a fixed horseshoe permanent magnet. The permanet magnet is adjustable to any required distance from the armature by means of a screw, and the electric currents are made to flow in one direction by means of a "dividor," which consists of a non-conducting collar fitted on to a brass tube fixed centrically to the armatures; one of the terminal wires is in connection with a brass semicircle on the collar, the other terminal wire is in connection with an opposite brass semicircle; two pairs of springs (fixed to the frame of the instrument by pillars containing binding screws), press alternately on the brass semicircles, one spring of each pair being on the wooden collar when the other is in contact with a brass semicircle, thus enabling each pair of springs to become a pole of the instrument, and a nearly continuous current of electricity to flow through the circuit when closed. Silvering, gilding, and coppering solutions, to be used in connection with the above magneto-electric machine, are described. The silvering solution consists of sulphite of silver (precipitated from the nitrate by sulphite of potash) dissolved in sulphite of potash, of which an excess is added. The gilding solution consists of oxide of gold (precipitated from a chloride by magnesia) dissolved in sulphite of potash, of which an excess is added. The coppering solution consists of carbonate of copper (precipitated from the sulphate by "carbonate of potassa") dissolved in sulphite of potash, of which an excess is added. The solvent solution above-mentioned (sulphite of potash) is made by passing sulphurous acid gas through a solution of pearlash, "taking care not to add sulphurous acid gas in excess.

A.D. 1842, September 8.—No. 9465.—Cooke, William Fothergill.—This invention "relates to the arrangement and disposition" of telegraph wires. The improvements consist of:—

Stretching, suspending, and insulating telegraph wires on posts and other suitable supports entirely of wood, or of wood and iron, erected at suitable distances. If the wires are required at an unusual height above the level of the ground, one pole is applied at the top of another in the manner top-masts of ships are placed on the lower masts, and they are properly stayed. To carry the wires beneath an arch, a piece or pieces of wood in an inclined position are used. The wires may either be placed one over the other, at one or both sides of the post, or on horizontal cross pieces fixed to one or more posts or supports. When the posts are necessarily at great distances apart, the wires may be kept at the required distance by glass tubes lashed to a bamboo rod. This improvement may be used alone or in conjunction with the methods of mounting and insulating telegraph wires set forth in Letters Patent, Nos. 7390 and 7614. At certain distances stronger posts are erected, to stretch the wire, so that they may hang parallel to each other. The following methods of straining the wires may be used:—"Winding up spindles with ratchet wheels and clicks," either fixed or removeable after the stretching; screw bolts and nuts with eyes to receive the wire; or "tackles or pullies in conjunction with holding tongs," or a bent lever in conjunction with a bolt having pin holes and an eye, may be temporarily applied; metallic contact between the wires being made through a piece of metal on which the ratchet wheels and clicks are mounted, or through which the bolts are fixed; or a copper wire may make metallic contact between the telegraph wires. Each drawing post may have stretching apparatus on one or both sides. When branch wires are required, the suspending or winding up apparatus on the nearest post must be mounted separately for each wire, so that the circuit is only completed through the signal apparatus. The insulation of the wires from the suspending and drawing posts, and from the earth, is accomplished by the following means:—The top of the post is enclosed in a wooden, glass, or earthenware case, the wires either being suspended on hooks outside the cases, or the cases having apertures for the wires; sheds may be used, with or without the cases, to "preserve a dry zone" around the posts between the wires, and one larger shed under the wires to keep them insulated from the earth; the wires themselves may be passed through tubes of glazed pottery-ware or glass, or a split goose quill fastened to the wire with white lead and twine; or the wires may be suspended under a shed by india-rubber loops and metallic S hooks; or the suspension hooks may be attached to glass tubes. The wires used may be either single wires of copper covered or not with thread and varnish, or iron wire painted and varnished; or compound wires of several wires twisted together with a central yarn of tarred hemp, or a central wire of copper, or a copper wire twisted amongst the iron wires may be used. The wire so stretched, suspended, and insulated, may be used for one half the telegraphic circuit, in conjunction with the earth circuit for the other half, instead of the "sixth wire" referred to in Letters Patent, Nos. 7390, 7614, and 8345. Distinct batteries may be used in conjunction with the suspension of the wires and the earth circuit, one to each wire, thus making as many electric currents available at one time as there are wires.

Communicating by electric means between any carriage in a railway train and the engine driver. Conducting wires, composed of two twisted copper wires woven into a web or threadwork, well coated with india-rubber, are extended over the tops of the carriages, and have branch wires proceeding to each carriage connected respectively with springs that can be brought into contact when required, thus actuating a battery and alarum (See Letters Patent, No. 7390) placed in the front carriage. A wooden roller (through whose pivots and standards the proper connections are made) is mounted over the alarum for the purpose of winding up the web.

The above-described improvements may be applied to communicating action from one regulating clock to other clock trains, to ensure their moving uniformly, also to printing telegraphs, and to releasing mechanism by means of electricity. Constant reference is made in the Specification to Letters Patent, Nos. 7390, 7614, and 8345.

BALLOON ASCENT FOR SCIENTIFIC PURPOSES.

At the last meeting of the British Association the balloon committee were charged with experiments to be made at times in the year and at times in the day at which no experiments have hitherto been made, particularly at night and in the winter months. No arrangement has as yet been made to take night observations, but those of the winter have been determined upon.

The first of these took place from Woolwich Arsenal on the 1st day of this month, and is thus described by Mr. James Glaisher:—In consequence of the balloon prepared for these experiments having been wantonly destroyed at Leicester, at a Foresters' fête, we are compelled to use the best balloon Mr. Coxwell has; with this we cannot hope to ascend more than 1½ miles or 2 miles; and if, as on this occasion, the course of the balloon is towards the sea, not even that elevation can be attempted but at the cost of the greatly abbreviated time for observation, and the sacrifice of all results excepting those connected with temperature. If with the small balloon our course should at any time be inland, both objects can be

secured by keeping the gas at the first part of the journey, and ascending to the limit to which the balloon will take us just before descending.

The balloon left at 2h. 37m., with a temperature of 48°, which remained unchanged till 600 feet were passed; it then declined gradually to 31½°. at the height of 5,200 feet by 2h. 58m.; on falling to 4,000 feet the temperature increased to 39½°, and declined to 30° at 5,000 by 3h. 26m.; on descending to 4,200 feet there was an increase of 2° and a decline to 29° to the height of 5,400 feet by 3h. 42m.; then a gradual increase to 41° at 1,400 feet; then no change on descending through the next 600 feet, when the last observation was made at 4h. 23m.; and we were on the ground at 4h. 25m., when it was too dark to read the instruments.

The temperature of the dew-point, or that temperature at which the water in the air is deposited visibly upon substances cooled down to that degree, as the bright metallic cups of a hygrometer, was 8° below that of the air from the earth to the height of 1,500 feet; the air then became much more humid, and at 2,100 feet the difference of these two temperatures was 5° only. On passing into a W.N.W. current, at 2,300 feet, the difference between these became 11°, and was nearly 20° at the height of 5,000 feet, when the air was very dry. On descending, the two temperatures approached again, and at 4,000 feet high were separated by 10° only. On again ascending, the difference increased to 23°, the temperature of the air being 32°, and that of the dew-point 9°, and it continued dry at high elevations. On descending below 3,500 feet, at 3h. 53m., the air again became humid, and continued so at all lower elevations, particularly between the heights of 800 and 1,200 feet, where the two temperatures were nearly alike, and the balloon was covered with water. Some strata of wet air were passed of no great thickness, without perceptible fog, depositing a good deal of moisture.

The reading of a delicate blackened bulb thermometer, placed in the full rays of the sun, which read 56° before starting, never read so much as 1° higher than another delicate thermometer, most carefully protected from the sun during the whole journey. The bulbs of these two thermometers were within two inches of each other. No tinge of ozone was shown throughout the journey. When at the height of 3,000 feet, the concussion from proving guns at Woolwich affected the balloon, and caused every rope to vibrate perceptibly and all the instruments to move, and this took place each time a report was heard, even up to the height of 5,000 feet. Once no less than three echoes were heard following a report, but usually one report only was heard.

A very delicate magnet, sent to me by Captain Evans, R.N., F.R.S., which vibrates in a little more than two seconds on the earth, was observed on ten different occasions, and the time of vibration appeared to be lengthened, notwithstanding the lower temperature of the higher regions. Another magnet, less delicately mounted, and which I have frequently used, also occupied a somewhat longer time in vibrating.

For an altitude of 20° all round there was mist; the remainder of the sky was for the most part clear. On examining the sun with a spectroscope over the earth, the colours of the spectrum were moderately bright; the line B at the red end, and G at the violet end, were the extreme limits, and there were not many besides the principal lines between; the wind was nearly W. near the earth. On reaching 1,100 feet we entered a S.W. current, and thought we should cross the river Thames north of Erith; but on passing above 2,000 feet we entered a W.N.W. current, and passed at 3h. some little distance south of Erith, and over Dartford at 3h. 16m., and here we saw the smoke from Gravesend passing southward, or S.S.W., till it reached 1,000 feet, and then to turn back upon itself. At this time, at the height of 5,000 feet, we were moving W.N.W., or towards Cobham Park. At 3h. 34m. we were south of Greenhithe, and nearly over Darent Wood. On examining the country, it had an appearance we had never seen before. At the height of a mile up to this time all hills have been dwarfed to level plains, and all valleys have been raised, so that the earth has appeared uniformly plain; on the contrary now, every variation of surface, every hollow, every rise were clearly shown; the course of the river Darent was traced for miles, with every elevation of land near it, but we could not see anything moving on the earth. The sun was shining, the sky was perfectly clear and of a deep blue. On examining the sun's spectrum here, it was ~~indeed different from below~~; the colours were all far brighter, the lines very numerous, extending from A at the red end to far beyond H at the violet end, which line was made up of fine lines. The spectrum was very fine. The sun was warm, but yet did not exercise any influence on the thermometer, upon the blackened bulb of which it shone brightly; at 3h. 46m. there was a sudden chill to sense; the wind was still W.N.W., and Mr. Coxwell, (who watched the direction and motion of smoke, the angle we made with known roads on passing them) with great judgment kept within its influence, so as to drive us inland, for, he remarked, if we sank to the lower current, to the sea we must go. At 3h. 58m. we heard a clock strike four. We were then a little south of Nursted. At 4h. we were south of Gravesend; at 4h. 17m. we crossed the Medway; then over Woldham, changed our direction to south-west nearly, and were on the ground at 4h. 25m., at Delce Farm, near Rochester, and received assistance from Mr. Matson, whose farm joined that on which we fell, for which we beg to thank him. The inhabitants at Gravesend and Rochester were greatly puzzled at our moving directly opposite to that of the wind where they were, and some thought we had a power of guiding the balloon.

During this ascent we hugged the river Thames all the way down. Mr. Coxwell felt that he dare not ascend higher than one mile, on account of the loss of gas we should have experienced in so doing, till we could pass Gravesend; and when we did so it was too dark. At 4h. 23m., at my last observation, it was very difficult to read the instruments, and it was then no use to ascend higher or to remain longer from the earth.

The balloon was seen from the Royal Observatory, Greenwich, at 2h. 40., when 1,000 feet high; it was watched by Mr. Nash till 3h. 8m., and up to this time he noticed that the balloon moved one-half round between 2h. 45m. and 3h., and then back again in the contrary direction; and at 3h. 8m. he could read the word "Mars" on the balloon distinctly with a telescope.

Simultaneous meteorological observations were made at the Royal Observatory, Greenwich, by command of the Astronomer-Royal, under the superintendence of Mr. Nash, and also at my residence by Messrs. Yair and Howe.

THE MANUFACTURE OF MAGNESIUM.

It is now pretty generally known that by a recent discovery magnesium can be used as an illuminating agent. Its properties in this respect are so great that photography, as applied to portraiture, can, with its aid, dispense with the light of the sun. It is not so generally known that the only establishment for the manufacture of the metal is in the borough of Salford. A few months ago it was stated in our columns that the existence of the metal was known to Sir Humphrey Davy more than fifty years since. He obtained it by electricity, in small globules, and his acquaintance with it ended there. Since that time magnesium has been produced by other chemists, usually by the action of electricity; but the metal has not, until within the last two years, been produced in such quantities as to make it available for the increase of the comfort or the luxury of mankind. It is now manufactured successfully, a second step in respect to it being thus made; and a further advance remains to be made, namely to discover to what purposes, other than photography, it may be applied. Mr. Edward Sonstadt, an English gentleman of Swedish descent, after much study and many experiments, recently discovered a comparatively inexpensive mode of making magnesium in large quantities. His patents for the process were purchased by the Magnesium Wire Company, whose works in Salford are the only manufactory of the kind in the world.

The basis of the manufacture is the mineral of which dolomite mountains are composed. It is found in the north-east of this country in combination with lime, constituting magnesian lime-stone, from which, however, the metal is not so readily extracted as from the carbonate of magnesium imported from Greece. There is also a range of hills in India that consists of carbonate of magnesium. In the ocean, magnesium exists in such quantities that Mr. Sonstadt estimates, if it could be brought together, it would make a mountain of magnesium more than fifty-four miles high, and as many square.

The process by which Mr. Sonstadt produces the metal is as follows:—The lumps of the carbonate of magnesium are placed in large earthenware jars with a quantity of muriatic acid. The solution thus obtained is drawn off when clear, and mixed with a solution of chloride of sodium or potassium. This mixture of magnesium and the alkaline chorides is subjected to heat in porcelain basins until the moisture is evaporated. The dried mass remaining is fused in a platinum crucible, and when poured out is technically known as "material." To deal with this a furnace is required, and the aid of sodium, which has already enabled chemists to obtain one of the latest metallic contributions to civilization, namely, aluminium. So important is the part played by sodium, that upon its price almost entirely depends the cost of magnesium. To make the latter cheap enough to be generally useful, it will be necessary to discover some less expensive mode than the present of obtaining sodium, and we believe this is likely to be done shortly. The "material" is placed in an iron crucible with a quantity of sodium, and heated to redness. The consequence is that the chloride of magnesium is decomposed, chloride of sodium is formed, and magnesium is liberated in its metallic state. The specific gravity of the metal is so light, being only 1·74, or little more than half of that of aluminium, that a large portion of the magnesium is found, when the crucible has cooled and been opened, on the surface of the salts, and in the form of compressed spheres. The remainder of the metal is held by the flux, in globules varying in size from that of a microscopic sphere to that of a nut. The metal thus obtained is still unfit for commerce, being brittle and unworkable. It has to be still further purified by distillation, and this is accomplished on the same principle (though necessarily on a much smaller scale), by which mercury is released from the ore cinnabar. An inverted iron jar rests upon the elongated cover of a small cast-iron box. A tube passes through the centre of the jar, and forms a communication between it and the box. The crude metal is placed round the tube, which reaches to within an inch of the lid, and the jar is placed in the furnace, the elongated lid of the lower box resting on the fire bars, and thus the box is below, and is comparatively cool. The heat volatilises the metal, which condenses in the lower vessel, and the product thus distilled is almost chemically pure. It should be stated that the air is excluded from these vessels; if it was admitted, the magnesium would burn.

The metal thus formed in solid blocks is taken to the Salford Ironworks, arrangements having been made by the Company with Messrs. Mather and

Platt for the conversion of the lumps of metal into wire and ribbon. The blocks are washed, to cleanse them from dirt and oxide, and are broken into small pieces. To convert these into wire an ingenious machine has been devised. The chief feature of it is a small hollow cylinder, adapted to receive a ram at one end, and covered at the other by an iron screen, perforated with two or more holes opposite the chamber. This press, as the cylinder is called, is subjected to the action of gas from a blowpipe, and the heat employed is only what suffices to soften the metal in the press. The small lumps of magnesium are thrust into the chamber, the ram is placed in the mouth of the press, and a pressure of between two and three tons (at present obtained by hydraulic apparatus, but which may, of course, be provided by steam), forces the ram against the softened metal, and the latter oozes in continuous strings of wire through the perforations already named. To make ribbon, the wire thus obtained is passed between two hollow, heated rollers, and is received in a flattened state upon a reel.

The only use, as we have stated above, to which the wire has been yet applied, has been for illumination. Mr. Brothers, of this city, was the first to adapt it for taking portraits by night; and in dull or foggy weather the burning of a small portion of the wire greatly assists the action of the sunlight for photographic purposes. Recently Mr. C. Piazzi Smyth, the professor of practical astronomy at the University of Edinburgh, sailed from Liverpool for Egypt. He has been supplied with quantities of the wire and every other requisite; and it is his intention to photograph the interior of the pyramids. It is manifest that such an undertaking can only be accomplished by an instrumentality like that which magnesium affords, and we wish the learned professor every success. By the aid of magnesium the interiors of caves and mines may be distinctly seen and photographed. For signals it is hoped that it will prove of great service. The magnesium light has been seen at a distance of twenty-eight miles at sea. Its applicability is now being tested in various ways by Government authorities and by chemists throughout the world; and we may confidently expect ere long many adaptations to use will be found of this practically new contribution to modern civilisation. Mechanical lamps have been devised for burning the wire, but at its present cost it cannot be extensively used for this purpose. The metal takes a fine polish under the burnisher; it does not clog the file; and when hot it is very malleable. Exposure for some time in moist air will tarnish it, but it is not affected by the action of sulphuretted gases. Articles of jewellery have been made from it, and a medal of magnesium has been struck; but its principal known use, as already stated, is as an illuminating agent.—*Manchester Guardian.*

CORRESPONDENCE.

MR. ROSENBUSCH'S NEW BATTERY.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I beg leave to bring under your notice, for the benefit of the readers of your journal, the description of a new kind of battery, which it is very easy to construct anywhere, and regardless of peculiarly shaped metals, and which entirely dispenses with the porous cell, the source of so much annoyance and resistance.

My battery is more or less analogous to that of Minotto, of Turin, but presents over this some marked advantages.

The outer vessel is the usual cylindrical glass jar commonly used for the Daniell battery. The positive element of the battery is a flat and very thin copper disc, to the middle of which is rivetted and soldered a copper wire, serving as electrode; this copper disc is placed horizontally at the bottom of the glass jar between two layers of sulphate of copper of one centimetre thickness each; the electrode is, therefore, in a vertical position, and in the axis of the glass jar. This copper electrode is surrounded with a tube of glass or gutta-percha of 1½ centimetre diameter, which reposes on the upper layer of sulphate of copper.

Over the two layers of sulphate of copper I place a disc of coarse linen, over this a thick layer of common sawdust, and then again a disc of coarse linen, on which latter reposes the cast zinc disc, which ought to be of nearly the diameter of the glass vessel, rather thick, and having a hole in the centre large enough to let pass the glass tube, which is firmly kept in the axis of the glass vessel by the surrounding sawdust and the zinc disc itself.

The object of this glass tube is to establish a communication with the lower part of the glass vessel, and to admit of adding sulphate of copper or water to compensate for consumption and evaporation.

The advantages of this arrangement are the following. I am enabled to *add* sulphate of copper to replace that consumed, and water to prevent the crystallization of the sulphate of copper, which otherwise, as in M. Minotto's arrangement, might form an impenetrable crust, which would entirely or partly suppress a communication between the two liquids and the metals placed therein.

The linen discs effectually prevent a mixture between the sawdust and the sulphate of copper.

No local action can take place as in the common Daniell, where the electrode of the zinc is generally a strip of copper soldered and rivetted to the zinc itself, which forms one of the weak parts of that battery, unless the contact place between the two metals is well coated with shellac or other isolating substance, which is a tedious and too often neglected procedure, because the electrode of my zinc is a narrow strip of zinc rivetted twice below the zinc disc, and again on the circumference of the same, thus ensuring an excellent contact.

The internal resistance of my battery can be varied at pleasure, be it by diminishing or increasing the layer of sawdust, or be it by increasing the size of the glass vessel and metals.

I beg to add, that I have experimented this battery for a long time, and have employed it (viz., 36 elements) to work a system of eight electric lantern clocks, in the town of Valetta, from 9th May, 1864, up to the present day, and intend to let it continue this incessant service to the end of the present year.

The only care bestowed on it has been to add from time to time some water to that in the zinc compartment, and to pour monthly some concentrated solution of sulphate of copper through the glass tube on to the copper disc, but even this slight inconvenience could be remedied by having a water bottle plunging into the liquid surrounding the zinc, which would supply the water as it evaporates.—I am, Sir, very faithfully yours,

EDWARD ROSENBUSCH.

Mediterranean Extension Telegraph Company,
27, Strada Stretta, Valetta, Malta.

THE ATLANTIC TELEGRAPH ENTERPRIZE.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—It was with more than ordinary pleasure that, on opening No. 47 of your interesting journal, I read the heading to one of the papers—"Atlantic Telegraph Enterprize,"—expecting, of course, a thorough account of the construction of the cable, &c., &c., so you may imagine my disappointment when, instead of a scientific treatise, I found a——I'll call it an essay, for such it appears, in more senses than one.

After reading the first few lines I skipped a paragraph, hoping to find that, like an organ-grinder with his monkey, "Amicus" was merely playing a prelude while the audience was collecting, before performing with the monkey, but for three weeks we have had to submit to his buffoonery. I could make nothing of it. It was a jumble of silly exclamations, would-be-funny sayings, with here and there a few technical terms which he has heard, and, parrot-like, repeats. He informs us, in paper No. 2, that he intends taking a plunge, and this he did with a vengeance, if we may judge by effect, for he certainly got out of his depth. He further tells us that he is young. Well, that, of course, is no reproach; nor can we blame him for wishing to appear in print; but, Sir, I think he might have chosen a more suitable place from whence to leap into immortality—for leap he must, if he will attempt it, since he is not yet in possession of the "pinions of Fame." One thing surprises me. It is that he should have had sufficient sense to conceal his name. I am forcibly reminded of those lines by Byron, ending thus:—

> "And yet, whoe'er he be, to say no worse,
> His name would bring more credit than his verse."

A new thought has struck me! Can it be that this is a practical illustration of some idea of his to make science amusing? We all know that young gentlemen of a certain age abhor anything appertaining to science on account of its supposed dryness; and many have resolved to reform and make grammar interesting. Who shall say what great inventions are not seething in the brain of "Amicus?"

I am, Sir, your obedient servant, J. P.

DANGEROUS CHIMNEYS.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Will you allow me an answer to a paragraph in your journal of the 26th ultimo, headed "Dangerous Chimneys." I cannot see how the cramps on a chimney-top can be a conductor, as they are generally let into the stone and covered with cement; even if they were exposed there is no connection with the earth, only the chimney, which is a bad conductor. As to gas being a good conductor of the electric fluid, how is it that when a chimney is struck the lightning never passes down the inside of it? I have seen a chimney that was struck which had four strong bolts twelve feet long connected with the cramps, and run down inside the flue of the chimney, and yet there was no trace of fluid inside; but there were large masses of stone cut out at intervals on the exterior of the chimney, from the top to the bottom. Again, there is a large number of chimneys with massive cast-iron cups or cornices, and they seem to escape the stroke as much as the stone or brick tops. But there need be no dangerous chimneys at all, if builders would only provide them with proper lightning-conductors.—Yours truly,

S. SANDERSON.

Victoria-buildings, Huddersfield, Dec. 3, 1864.

A NEW INVENTION FOR EXTINGUISHING FIRES.—A new invention for extinguishing fires has just been tried at St. Petersburg. About 130 lbs. of a white powder were dissolved in a vessel containing 200 gallons of water. A large wooden building two storeys high was then set on fire, and the liquid being pumped on the flames, they were extinguished without the least generation of vapour or smoke. The wood attacked by fire was covered after having undergone the action of the liquid, with a light coating resembling varnish.

TELEGRAPHIC NEWS.

New Zealand Telegraphs.—The receipts of the Canterbury line of telegraph for the year ending 30th June last amounted to the sum of £2,226; for the corresponding period of the previous year £800.

Indo-European Telegraph.—This line is complete between Bombay and Teheran, and works satisfactorily. Teheran is in communication with St. Petersburg, but the working of the line through the Russias cannot be relied on.

Failure of a Telegraph Cable.—Our Parisian correspondent writes on the 7th instant:—"I am informed that the Italian Government submarine telegraph cable from Cagliari (Sardinia) to Urepani (Sicily) ceased to work on the morning of the 30th November last."

Electric and International Dramatic Club.—An entertainment will be given by the members of the above society of amateurs on the 15th instant, at the Cabinet Theatre, Liverpool-street, King's-cross. The programme is of a very attractive character, and includes a performance of "Advice Gratis," "Done on Both Sides," and the "Artful Dodge." A notice of the entertainment will appear in our next.

Indian Telegraph Lines.—The *Bombay Gazette* announces that a violent gale has destroyed all the lines, including the span across the Kistna (Deccan). Communication has ceased in every direction. Masulipatam is reduced to a complete wreck by an inundation. Thousands of lives lost. It is rumoured that the telegraph-office is destroyed. Steps taken to re-establish communication on the 2nd November, and arrangements made to open a temporary office on the opposite bank of the Kistna.

The Overland Telegraph to America.—At a dinner given in honour of Dr. Rae's visit to Victoria, the gallant explorer said, "As to the telegraph, to show that it was a *boná fide* scheme, he might state that 600 miles of wire had already been landed in Canada, 600 at Yorke Factory, Hudson's Bay, and 600 miles more were *en route*. The connection would be made through from Canada, if the Government of the provinces would assist the undertaking; and if not, the line would still be carried on from Red River.

Serious Accident to a Telegraph Clerk.—On the morning of the 1st instant, an accident occurred at Greenhill Junction, near Denny, by which a young man named David Sheppard, telegraph clerk, was seriously injured. It would appear that he had got upon an engine which was employed shunting waggons, and in leaping off while it was in motion, he did so with his face towards the tender, and was thrown violently to the ground. The consequence was that he was completely stunned, and his right arm falling upon the rails one of the wheels passed right along it from the hand to the shoulder and crushed it to a perfect jelly. Drs. Benny and Cuthill from Denny were soon in attendance, and with the assistance of other two medical gentlemen from Falkirk, amputated the injured limb.

The Telegraph at Paraguay.—From Paraguay it is announced that the telegraph wires were laid down to Villetta, and opened to service on Sunday, the 16th October. The first despatches sent were the following:—"To His Excellency D. Francisco S. Lopez, President of Paraguay.—Telegraph Station, Villetta, Sunday, October 16, 7.15 A.M.—With great joy and profound respect, I send your Excellency the first despatch of the telegraph wires in Paraguay, with my sincere congratulation for the happy anniversary of the second presidency. May God preserve you many years.—Hans Fischer." ("Received R. T. Truenfeld.") "Government House, Asuncion, October 16.—His Excellency President Lopez has received with great satisfaction the first telegram, dated at 7.15 this morning, from Villeta, commemorating the Presidential anniversary, on occasion of inaugurating the telegraph wires in the republic. His Excellency desires me to congratulate and thank Mr. Hans Fischer, as also the director, Mr. Truenfeld, and staff of the telegraph company, for the happy issue of their labours.—Francisco Sanchez."

The Telegraphic News Association, Limited.—This company, with a capital of £50,000 in £5,000 shares of £10 each, proposes to furnish the press and the public of England, the continent of Europe, and the Western world with a fuller and more regular supply of telegraphic intelligence than the present system provides. The promoters state that, after much preparation and expenditure, and favoured by circumstances of an exceptional nature, they are in a position to undertake this responsible function with the certainty of being able to execute it in a complete and effective manner. Distributed at all points within the range of the electric wire, where the most important intelligence, political and commercial, is to be obtained at first hand, a staff of experienced correspondents has been organised, whose established relations with authentic sources of information insure a priority of intelligence upon which implicit reliance may be placed, and whose tried discretion and activity offer the safest guarantees for despatch and punctuality. Special arrangements have been made for procuring early and accurate, and in many instances exclusive, information in connection with the American civil war, and the progress of the new Mexican empire; while from China and the East Indies intelligence will frequently be transmitted, *viâ* St. Petersburg, when other sources of information are silent. A careful estimate has been made of the probable financial results of the undertaking, assuming the highest scale of expenditure and the lowest of receipts. The conclusions arrived at justify the anticipation of a large return upon a small outlay. The head office of the Association for England and the Western World will be in London, and for the Continent of Europe in Brussels. There are several good names on the list of directors, and with fair management this project may prove very successful.

Fire in the Leeds Office of the United Kingdom Telegraph Company.—In the afternoon of the 4th instant, a fire broke out at the office of the United Kingdom Telegraph Company, Park-row, Leeds. It appears that shortly after one o'clock, as a man was employed coating with gutta-percha several of the wires in the test-box, the lighted naphtha lamp which he used in the operation accidentally fell from his hand and ignited the gutta-percha. In an instant the wood work of the test-box was on fire, which rapidly communicated to the surrounding articles, and before the brigade could be procured the office was filled with smoke and flames. On the arrival of the firemen an abundant supply of water was found on the premises, and the conflagration was extinguished before much damage was done to the valuable telegraphic instruments—twenty-two in number—which were in the room where the fire originated. The immediate result of the fire was to injure the wires connecting the instruments with the exterior wires, and thus to stop all communication; but this was quickly obviated so far as London was concerned by the somewhat novel expedient of conveying an instrument to the roof of the premises, and placing it in connection with the wires which hang immediately above. The damage is estimated not to exceed £20. We understand that communication with all the company's stations was resumed on the morning of the 5th instant.

The Persian Gulf Telegraph.—The following communication has been received in reference to the Persian Gulf telegraph, from Major J. U. Champain, R.E., Director Persian Telegraphs, to the Chief Secretary to the Government of Bombay:—"Teheran, September 27, 1864.—Sir, I have the honour to report very briefly, for the information of the Government of Bombay, that the line of telegraph is now completed between Bushire and Teheran, and works most satisfactorily. Between this and Bagdad some ten days' work remains to be done; but we shall not be allowed to join up the wires, which have been cut near the frontier of Turkey, until the boundary question has been decided. I shall, however, try to organise a system of Sowars to carry messages between Kasr Sheereen and Khanakin (a distance of twenty miles) three or four times a day. In case I succeed the expenses will be a mere trifle, and messages between England and India would not be delayed more than three or four hours at the frontier. Should this proposal not be agreed to, important messages can still be sent to England *viâ* St. Petersburg, which is now in telegraphic communication with Teheran. I shall have the honour to submit my detailed report of operations in connection with the construction of the Persian line as soon as it is entirely completed. I have the honour to be, &c., J. U. Champain, R.E., Director Persian Telegraphs."

The Indo-Ottoman Telegraph.—A convention has recently been concluded between her Majesty's Government and the Porte, on the subject of the Indo-Ottoman Telegraph. The Ottoman Government binds itself, at its own expense, to extend and keep in repair to the mouth of the Shatt-el-Arab the great telegraphic line now completed from Scutari to Bagdad, and to connect the line in the direction of Khanakin with the Persian wires now communicating with the submarine cable at Bushire. The Indian Government on its part is to make a line from some point of British India to the mouth of Shatt-el-Arab. At the latter point a mixed station is to be established for the exchange of messages. The Turkish Government is to have officials acquainted with the English language. Art. 9 provides:—It is agreed by the high contracting Powers that the charge on the Indo-European despatches transmitted on the Ottoman lines of Asia through the entire course between Constantinople and Fao, or to the Persian frontier, in the direction of Khanakin, and *vice versâ*, shall not exceed 22f. 50c. or a simple message sent from Constantinople to Khanakin, or *vice versâ*; and similarly, that the charge on the despatches, by the entire submarine line from India to Fao or to Bushire, and *vice versâ*, shall not exceed, the first the sum of 62f. 5c. and the last that of 50f. for a simple despatch.

MISCELLANEA.

Curious Natural Phenomenon.—A writer in the *Zoologist* for November states that the Channel Islands are gradually sinking into the bed of the sea.

The India Rubber, Gutta Percha, and Telegraph Works Company.—During the past few weeks one of Gisborne's ship-steering telegraph instruments has been in operation at the offices of the company, and thousands of persons have crowded round the window in Bishopsgate to get a glimpse of the apparatus, which is at work showing the various signals, by means of a current conveyed from some distant part of the building.

The Last Folly of The French.—Common fame asserts that the silent system is about to be introduced into the club life of Paris, possibly as a punishment for the numerous scandals which daily issue from those select societies.—"Le Club Muet" is to be the title of this rather novel place of social meeting. Conversation is to be allowed on the steps; and members will be permitted to ask for letters in the hall; but once the door which admits him into the "realms of silence" has swung behind the elected member, he must not speak! He may eat, drink, sleep—if he does not snore—play whist, and smoke. He must not, however, indulge in dominoes, or "call the rattling main." Of course, if Pedro do Ponce had been alive, he would have been the active member of the committee of this secret society. It will be a droll sight to see the good company telegraphing for their dinner, and finding fault by signals with a bad cigar or a corked bottle.

THE EXPORTS OF INDIA-RUBBER AND GUTTA-PERCHA FROM SINGAPORE.—The value of caoutchouc exported from Singapore to the United Kingdom in 1861 was £95,116 against £70,413 in 1862, thus showing a decrement of £24,703. The value of gutta-percha exported in 1861 was £124,318; in 1862, £155,397 giving an increase of £31,079.

A NOVEL PRESENT.—A miniature telegraph office, designed for a present to the Emperor of Russia, has been prepared by an artizan of New York city. It consists of a complete telegraphic apparatus, capable of transmitting messages between New York and Boston, all embraced within the compass of a morocco case eight inches in length, six inches in width, and three and a half inches in depth.

PREPARATION AND PURIFICATION OF MAGNESIUM.—Mixed solutions of chloride of potassium and chloride of magnesium are evaporated to dryness, and thus a non-aqueous double salt is obtained, which, when reduced with soda in an iron crucible, yields large quantities of magnesium. It may be purified (though for photographic purposes this would be superflous, and enhance the cost of production considerably), by distillation in an iron apparatus filled with hydrogen.

A SUSTITUTE FOR INDIA-INK.—A substance much of the same nature and applicable to the same purposes as india-ink may be formed in the following manner:—Take of isinglass three ounces: make it into a size by dissolving over the fire in six ounces of soft water. Take then Spanish liquorice one ounce, dissolve it in two ounces of soft water over the fire in another vessel, then grind up on a slab with a heavy muller one ounce of ivory-black with the Spanish liquorice mixture. Then add the same to the isinglass size while hot, and stir well till thoroughly incorporated. Evaporate away the water, and then cast the remaining composition into a leaden mould slightly oiled, or make it up in any other convenient way. This composition will be found quite as good as the genuine article. The isinglass size, mixed with the colour, works well with the brush. The liquorice renders it easily dissolvable, on the rubbing up with water, to which the isinglass alone would be somewhat reluctant; it also prevents it cracking and peeling off from the ground on which it is laid.—*British Journal of Photography.*

THE ELECTRIC LIGHT FOR LIGHTHOUSE ILLUMINATION.—The magneto-electric light, invented by Professor Holmes, and tried in 1858 at the South Foreland, has been in constant use at Dungeness since 1862. At this place there are in the lantern two lenses, fixed one over the other, and two regulators to each. It appears from Mr. Holmes's statement, in a discussion at the Society of Arts, that only one light is shown at a time, but there are two regulators for each lens, so that an instantaneous change from one to the other can be made without extinguishing the light when fresh carbons are required. Two magneto machines are placed in the machine rooms. A steam engine forms part of the apparatus required for producing the electric light, and at Dungeness a direct-acting steam-engine and two boilers are attached to each magneto-electric machine. These machines contain 120 horse-shoe magnets, of about 50lbs. each in weight, and 160 helices. Mr. Holmes states that the light thus produced has all the steadiness and uniformity required for lighthouse purposes, and has this decided claim over other systems—it can be extinguished in an instant. One obvious disadvantage in the magneto-electric light is that in consequence of steam power being required it cannot be brought into practical use on rock stations, such as the Eddystone or Bell Rock.

A NEW THERMOGRAPH.—M. Marcy has addressed to the Academy of Sciences the following description of an instrument for marking small variations of temperature:—1. The first part of this thermograph consists of a copper tube a metre in length, the interior diameter of which is capillary, not being more than one-fifth of a millimetre. It is open at one end, and soldered to a hollow copper ball at the other end. 2. The second part of the apparatus consists of a wheel resting upon knife edges, like those of a pair of scales, whereby a very delicate oscillation may be imparted to it. The axle of the wheel carries a long vertical needle, marking the degrees on a circular scale. To the circumference of the wheel is fixed a glass tube six millimetres in diameter, and bent in conformity to the curvature of the wheel, and so situated that the middle of the tube lies vertically underneath the needle when the wheel is at rest. One of its extremities is hermetically closed, while the other is open. Now, if a little mercury be poured into this tube it will settle at the lowest point, and the interior of the tube will thus be divided into two chambers, one closed and with air confined in it, the other open. 3. Now introduce the copper tube into the glass one, giving it of course the same curvature, and so that its extremity may pass through the mercury, thus establishing a communication between the hollow copper ball and the confined chambers, and the apparatus, with a few accessory appliances, will be complete. The end of the copper tube dipping into the mercury should be varnished to prevent its being attacked by the latter metal; or better still, the end might be made of platinum. 4. To use this apparatus, put your hand to the copper ball; the warmth thus imparted to it will dilate the air it contains, and drive part of it into the confined chamber; the mercury will therefore recede, and thereby make the wheel turn round its centre of gravity; the very small arc thus described will be revealed by the needle, the difference of its present position with its previous one when at rest. If, on the contrary, the copper ball be cooled, by water for instance, the air inside will be contracted, a portion of the air of the confined chamber will rush in, and the mercury will be driven forward, the needle turning in the inverse direction. By means of this experiment very delicate physiological experiments on animal heat may be conducted.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

2980. A. E. Dobbs, B.A., taking deep sea soundings without the use of a line, and for bringing up specimens of the sea bottom and sea water from the greatest depth.

2997. J. Sax, the improvement of electric fire buttons and indicators, capable of being used in private houses, public places, on board ships, and on railways.

3016. J. W. Proffitt, improvement in railway carriage and passenger signals.

GRANT OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2826. C. Cotton and W. Nunn, improvements in apparatus for facilitating communication between passengers and guards of railway trains.

PATENT SEALED.

1442. J. Williams and T. Robinson, improvements in annealing wire.

IGNORAMUS.—The metre is 3·280899 feet, or 39·37079 inches.

J. H. S.—We know of no special "insulating ink." Bakewell interposed a *varnish* writing between a style and tinfoil in his "copying telegraph." Caselli employs the common ink of commerce in his "pan-telegraph," with a full proportion of gum in it, which is found to insulate sufficiently for the purpose. It should be mentioned that the pressure of the style in the latter instrument is very trifling, it being only a thin platinum wire.

*** We shall feel greatly indebted to our readers, both at home and abroad, for any information which it may be in their power to render with respect to telegraphic progress.

Communications intended for publication must be authenticated by the names and addresses of the writers; not necessarily for insertion.

Letters relating to Advertisements are to be addressed to the Publishers. All other letters and communications to be addressed to the Editor of the *Telegraphic Journal*, 4 & 5, Suffolk-lane, Cannon-street, London, E.C.

The *Telegraphic Journal* can be had of Messrs. SMITH & Co., Strand; J. ONWHYN, Catherine-street, Strand; Messrs. DAWSON & Co., Cannon-street, E.C.; Messrs. KENT & Co., Paternoster-row, London. Messrs. HEYWOOD & Co., Manchester; at the various railway stations; and of all news-agents, &c., &c.; or it can be supplied, if preferred, direct from the Office on the following terms:—

Quarterly, 4*s.* 4*d.* | Half-yearly, 8*s.* 8*d.* | Yearly, 17*s.* 4*d.*

TO ADVERTISERS.

Clerks, assistants, manipulators, and instrument makers, seeking employment, &c., will find the *Telegraphic Journal* a ready means of making known their requirements.

The *Telegraphic Journal* is the most effective medium for inventors, patentees, contractors, manufacturers of insulating materials and electrical apparatus to submit their various specialities to the consideration of secretaries and managers of telegraph or railway companies, and other persons engaged in electrical and telegraphic pursuits.

Advertisements must be delivered to ensure insertion before SEVEN O'CLOCK on Thursday evening in each week. The charges for Advertisements are—

	£. s. d.		£. s. d.

ON RAILWAY ELECTRIC SIGNALLING.

By W. H. Preece, Assoc. Inst. C.E.

(*Concluded from page 280.*)

There are various places on a double line which require special arrangements differing from the method above described for carrying out the block system. These are junctions, inclines, and mineral sidings. Long tunnels are worked precisely as a single section of the block system.

JUNCTIONS.

The system gradually being introduced on all railways to protect the traffic through junctions, is to maintain the fixed signals at such places always at danger, and not to lower them until a train approaches, or until they are whistled down by the driver, and by combining the points and signals in such a way, that while they work in unison the other signals and points are locked. Thus, when the branch signal is lowered for the admission of a branch train, the main line signals and points are locked, and cannot be altered. It is a system highly conducive to safety, and reflecting great credit upon its inventors and introducers, Messrs. Saxby and Farmer, It was first used on the Brighton line, and is now being gradually introduced on all important railways. It has, however, the great disadvantage common to the "affirmative" system, that the danger signal may be exhibited when no danger really exists, and thus gradually instilling a disregard of its warning on the part of the driver. Now, the advantage of the addition of electric signalling to this system is, that by giving ample warning of the approach of a train, it prevents the unnecessary exhibition of the danger signal. At junctions the electric signals are placed upon the same footing as the fixed signals: they are constantly maintained at danger, and are only lowered on the receipt of the warning signal (Rule 2) when the line be clear. The special instructions at junctions are as follows:—

1. The electric signals are to be always maintained at *Danger*, except when taken off by the junction signalman to admit a train or engine.
2. On the receipt of the signal "Train coming: be ready" (*vide* Rule 2, General Instructions), the junction signalman will, *should the line be clear*, lower the signal for that section to "all clear," but should the line *not* be clear, he will give the obstruction signal on the bell (*vide* Bell Code, No. 5).
3. On the approach or arrival of the train or engine at the station, *provided the electric signal be at "all clear,"* it must be signalled to the junction signal box upon the bell (*vide* Rule 3, General Instructions).
4. The signalman at the junction box will acknowledge this signal by restoring the electric signal to danger, and then, *but not till then*, he will lower his fixed signals.
5. No signal is to be considered complete until it has been acknowledged.

Now, apart from the warning of the approach of the train which is given by the above system, and the consequent preparation made for its passage, the additional security is obtained of a second distant signal at the next station from the junction. Where these stations are far apart, the train can be sent on under the "caution" signal, the driver having been warned of the junction being closed; but, as a rule, junctions are near stations, and there is no necessity for departing from the rule. On a busy and important line it would be advisable to insert an intermediate box if the stations be distant. I have arranged the switches (Fig. 6) of the junction signals so that they lock each other. The movement of one switch from ON to OFF renders the others fixtures. Thus, when the electric signal is lowered for the admission of a branch train, both the up and down main lines are blocked not only at the fixed signals, but on the electric signals also. Under this system the junction is worked as effectively and as safely as any section of the line regulated by the block system. Collisions are impossible, the security of Saxby and Farmer's junction signals is doubled, and *the danger signal is never exhibited except when actual danger exists.*

Of course this system can be applied to junctions whether the line be worked on the block system or not, and upon whatever principle the signals be fixed. It affords a security which no other means of working can possibly supply. Where the block is not used, the above instructions will not apply; but it is only necessary to suppress the warning signal, and slightly modify the other rules, to suit the altered circumstances of the case.

INCLINES

Are worked upon precisely the same system. The signals—electric and out-door—are maintained at "danger;" and permission for trains to descend or ascend is not given until the line is clear, and the signals lowered for that purpose. The instructions framed for this purpose are as follows:—

1. The signals are to be always maintained at *Danger*, except when taken off to admit a train or engine.
2. When a train is ready to descend or ascend the incline, the signalman will signal its approach—"Train coming: be ready" (*vide* No. 9, Bell Code).
3. The signalman at the other end will then, *should the line be clear*, lower the electric signal to "all clear" for the admission of the train; but should the line *not* be clear, he will give the obstruction signal (No. 5, Bell Code).
4. When the line is clear, and the electric signal is lowered, the train will be allowed to proceed, and it will be signalled—"Train in." (No. 2, 3, or 4, Bell Code).
5. The electric signal will then be again restored to danger.
6. No signal must be considered complete until it has been acknowledged.

MINERAL SIDINGS.

One of the most dangerous and complicated points in the management of the traffic on a busy line in the manufacturing and mining districts, is the proper arrangement of the signals at those numerous sidings and junctions with mines, collieries, works, &c., which feed and intercept the main lines at so many spots. It is the custom upon most railways to protect these sidings by distant signals only, and to place these signals at danger before allowing anything to enter or block the main line; but, as under the time system, drivers grow indifferent to the indications of distant signals, cases have occurred where these signals have proved insufficient for the purpose. Fixed standard signals are now being introduced, and all busy sidings are worked precisely as junctions. There are many places, however, where the traffic from the siding is not sufficient to maintain a signalman constantly employed, and where men are temporarily detailed to perform the duty of admitting trains out of and on to the main line. Where the time system is employed, the traffic regular, and such shunting is performed according to the service time tables, it may be conducted with ample security by means of fixed signals; but where the block system is in use, and the traffic is irregular, additional safety is essential. Now, electric signalling offers a ready means to conduct the business of a mineral siding with perfect security. It enables the signalman at the siding, whether permanently employed there or temporarily detailed for shunting duties, to inform the stations on each side of the

siding of the readiness of a train or engine to enter the main line; the signalmen at these stations are thus enabled to block the up or down line, or both, as may be required, and to give permission for the mineral train to leave the siding under perfect protection. The charge of these points are therefore under their supervision, and not under that of the man at the siding, and the safety of the traffic is secured. To do this effectually, it requires a bell communication between the siding and the station on each side, and two semaphores in the siding box—one worked from the one station to protect the down line, and the second worked from the other station to protect the up line. The switches working these semaphores would be locked with the main line switches, so that it would be impossible to lower them together: the "all clear" signal for the train to leave the siding could only be given when the main line signals were blocked. Supposing a train be waiting upon the siding which is upon the down side to enter the down line, the man at the siding would signal upon the bell to the signalman having the protection of the down line—"Down train waiting to come out." This man would then by his bell and semaphore block the down line, and lower the semaphore at the siding for the train to come out. He would maintain the block until the train reached him. Supposing the mineral train were to enter the up line: to do so it would cross both lines, and therefore both lines should be blocked, The man at the siding would signal—"Up train waiting to come out," and the signalmen at each end would block their own lines before permission was given him to come out. That this can be done with ample security and perfect confidence requires no further proof on my part. I cannot give a code of instructions for this particular service, because it would depend so much upon the particular locality and the nature of its traffic, but regulations can easily be framed from the preceding remarks and instructions which have been already given, to suit any point, and meet the emergencies of the traffic at that place.

The next and last point that I shall discuss regarding the adoption of electric signalling into railway working, is the protection it affords to the proper regulation of trains on

SINGLE LINES.

It is in the working of single lines that the application of electricity demands the earnest attention of railway managers. Where more than one engine is employed, the use of the telegraph is rendered compulsory by the Board of Trade. Indeed, it may be said with truth, that this department of Government has devoted more care to the protection of the public in travelling over single lines than to any other branch of railway working. They have issued a most carefully constructed code of regulations for the working of single lines upon the train-staff system; and, it must be admitted, that if this system be regularly adhered to, collisions would be impossible on single lines. But railway managers are at variance not only with the Board of Trade, but with themselves, upon the advantages of the train-staff system. Captain Huish said,* "The only way by which a single line could be worked with absolute safety was by the train-staff." But Mr. Hemans stated, that he had found from experience that it was exceedingly defective, and that when running only four trains per day in each direction on a line of seventy-five miles, that it was next to impossible to repair defects on the line without working in the middle of the night, owing to the difficulty of getting the "train-staff" from passenger trains for the use of ballast trains; and he was convinced that electric signalling, when perfected, must be adopted to develop traffic on single lines. It is perfectly true, as Captain Tyler remarked at the same meeting, that no accident had occurred from trains meeting one another where the staff was employed, but that where telegraph instruments were employed without the staff there had been numerous accidents, in consequence of mistakes and misunderstandings on the part of the persons in charge of the instruments. The principle of the train-staff is undoubtedly sound in theory and conducive to safety; but experience, which, after all, is the true test of theory, has proved it to be impracticable. I know of no long length of single line that is worked by the staff. Mr. Hawkshaw, the then President of the Institution of Civil Engineers, admirably summed up its merits in the following words:—

"Theoretically, no doubt the train-staff led to greater safety than any other mode of working. But persons might be preserved from railway accidents by not going upon a railway at all; and the train-staff was doing away with railway travelling. As a system it simply meant that, provided a company confined itself to one staff, it would also limit itself to one locomotive; and so long as only one locomotive at a time ran upon the line there could not be any collision. But it was obvious that under that system trains could not be started from the same end of the line at short intervals of time; as when the staff was at the other end it must be brought back, and this necessarily involved delay. He considered the train-staff system was wholly inapplicable to any railway on which the traffic was large."

It frequently happened on the Epsom and Leatherhead line of the London and South Western Railway that a man had to be sent on horseback, or by carriage, to the other end of the line to obtain the staff.

It therefore appears that while the train-staff is correct in theory, it fails in practice, and therefore that some other system is required, to give railway managers the security of the train-staff without its disadvantages. Now, the security of the train-staff is this: it renders impossible the collision of two meeting trains upon a single road. If, therefore, we can by any other system render this meeting of two trains equally impossible without the necessity of stopping trains to exchange staves, or delaying trains to wait for the staff, we shall obtain the advantages of the train-staff without its inconveniences.

We obtain this by electric signalling. The security which the block system gives to the traffic of a double line from the danger of the collision of following trains, affords the same protection to single lines from the collision of meeting trains. By means of the electric signal checked by its repeater, a danger signal can be raised at the station in advance, which is not only a protection in itself, but which is a more certain security from accident than the staff. Engine drivers have been known to start without the staff, because they know that no other train can have it before them; but no driver, however reckless he may be, has ever been known to drive a-head in the face of a danger signal on a single line. It is a well known fact, that drivers are far more timid on a single than upon a double line. They know nothing will meet them on a double line, and they always expect to pull up before they come to danger; but on a single line, unless running under a very well regulated system, they lose that recklessness and daring which is so characteristic of them on a double line. I, therefore, contend that there is less fear of the danger signal being disregarded on a single line by a driver than of his proceeding without the staff; and that electric signalling offers a more effective security from the collision of meeting trains on single lines than the train-staff, without any of its inconveniences or delays.

The instructions under which a single line is worked by electric signalling are as follows:—

1. No train or engine is to be allowed to pass your box unless the electric signal for the section into which it is about to proceed stands at ALL CLEAR, and the line has been *blocked* at the station in advance, thus:—

2. On the arrival of a train or engine at your box, you will, provided the electric signal stands at ALL CLEAR, at once signal to the next station in advance—"Train coming." (No. 9 Bell Code.)

* Vide Min. Inst. Civil Engineers, 1862-63, Preece on "Railway Telegraphs."

3. You will then place your switch-handle at ON, thereby placing the electric signal at the station in *advance* at DANGER, and preventing another train from *meeting* that entering the section.

4. The station in advance will, before acknowledging the above signal, put on the danger signals—station and distant—against trains coming in the opposite direction to that from which the train is approaching his station, and keep such signals on till that train arrives, and the section is clear.

5. On receiving the acknowledgment to the above signal the train may enter the section. (No. 2, 3 or 4 Bell Code.)

6. The arrival of the train at the station in advance will be signalled—"Line clear; train out." (Bell Code No. 10.)

7. You will then remove the electric *danger* signal, and clear the line.

8. No signal is to be considered complete until it has been acknowledged.

NOTE.—These signals are not intended to alter or supersede the working arrangements already in use for altering the meeting places, but to prevent (as they will prevent) two trains on a single line meeting each other between any two stations.

It will thus be seen that before a train is allowed to enter a section of line, it is carefully blocked in advance both by the electric and fixed signals, and that under such circumstances the train can proceed with absolute safety. The system admits of no mistake. The signals cannot be completed unless they have acted properly, and until they are completed the train does not move. Trains can follow each other in rapid succession either upon the *space* or the *block* system, for no train can start in the opposite direction until the signals are lowered by the first station. Trains need not be stopped to effect this. When they are not stopping trains, the line is blocked in advance, and cleared for their entry on their being signalled from the previous station. The train-staff cannot do this. It is true that by the aid of tickets and passes following trains can proceed after each other in any number, but the staff which comes last rules supreme, and cannot be given up without delay to allow a train to proceed in the opposite direction. When ballasting trains, specials or irregular traffic occur, the inconvenience is excessive. As the NOTE remarks, the electric signals do not in any way interfere with the existing arrangements for altering the crossing places of trains; on the contrary, they render the system of altering the meeting places doubly secure. All the accidents that have taken place upon single lines, alluded to by Captain Tyler as occurring where the train-staff was neglected, and where the electric telegraph was employed, have arisen from errors or misconceptions in the wording or meaning of the telegrams. On the Shrewsbury and Hereford Railway a collision with loss of life occurred from the insertion of the word "*at*" in the copy of a telegram, and from the general want of explicitness in the wording of the message itself. On a railway in the north of Scotland the superintendent was himself killed in a collision caused by his own irregular orders. On the Monmouthshire Railway a collision occurred from the error of a telegraph clerk in mistaking an ordinary engine for a pilot engine that was expected.

Now, the train-staff or electric signals would have saved all these accidents by protecting the line for the passage of the train from any meeting train, and by affording a secure check from any error in the electric telegraph. Errors in telegrams can only be protected against by adopting additional and independent precautions; and I maintain that electric signalling affords this protection as securely and as completely as the staff, without any of its inconveniences and disadvantages. It is, indeed, the principle of the staff differently carried out.

The use of electric signalling in no way interferes with the general auxiliary character of the telegraph which is so useful in giving notice of the delay of trains, in hurrying on one train and stopping another, in altering as required the authorised passing places, and preventing the unpunctuality of one train from affecting all the rest. It only makes these operations more secure, and renders the effect of any error or misconception in the wording of a telegram harmless and innocent.

I have now completed my description of electric signalling and its various applications to the different requirements of railways. I have confined myself solely to the system I have patented and introduced upon the London and South Western Railway; but my remarks can be applied to most of the systems in use, or perhaps the systems might be applied to my remarks. I believe I have eradicated most of the objections raised against existing systems in the instruments I adopt, but I may have introduced others that I am unaware of. However, I have done my utmost to place electric signalling on its proper footing, and to show railway authorities what a power it affords them to expedite traffic, secure safety, and instil confidence into the mind of the public.

THE ATLANTIC TELEGRAPH.

A CONTEMPORARY, adverting to the Atlantic Telegraph enterprise, makes the following observations as to the progress now being made in the manufacture of the cable, and the arrangements entered into to secure its stowage on board the Great Eastern, and its successful submergence from the hold of that vessel:—

The distance from the western coast of Ireland to the spot in Trinity Bay, Newfoundland, recently selected as the landing-place for the new cable, is a little over 1,600 nautical miles, and the length of cable contracted for to cover this distance, including the "slack," is 2,300 knots, which leaves a margin of 700 knots to cover the inequalities of the sea-bed, and to allow for contingencies. On the first occasion, 2,500 statute miles were taken to sea, the distance to the Newfoundland terminus on that occasion being 1,640 nautical miles; and, after losing 385 miles in 1857, and setting apart a further quantity for experiments upon paying-out machinery, sufficient new cable was manufactured to enable the Niagara and Agamemnon to sail in 1858 with an aggregate of 2,963 statute miles on board the two ships, of which about 450 statute miles were lost in two first attempts of that year, and 2,110 miles were finally laid and worked through.

The greatly increased weight and dimensions of the present cable would have made the question of stowage a very embarrassing one had it not been for the existence of the Great Eastern steamship, there being no two ordinary ships afloat that would be capable of containing, in a form convenient for paying out, the great bulk presented by 2,300 miles of a cable of such dimensions. This bulk, and the now acknowledged necessity for keeping cables continuously in water, have indeed made their influence to be felt in a very expensive manner to the Company and to the contractors throughout the progress of the work even at this early stage. The works at Morden Wharf have had to be to a very large extent remodelled to meet these contingencies Eight enormous tanks, made of five-eighths and half-inch plate iron, perfectly watertight, and very fine specimens of this description of work, have been erected on those premises, into seven of which the cable is now daily being coiled as it comes in its completed state from seven corresponding closing machines. An eighth closing machine will soon be added, and these tanks will then receive an aggregate of 80 miles per week. Four of the tanks are circular in shape, and will each contain 153 miles of cable, being 34 feet in diameter, and 12 feet deep. The other four are slightly elliptical, being 36 feet long by 27 feet wide, and 12 feet deep, and will contain each 140 miles. The contents of all these, as they become full, will have to be transferred to the Great Eastern at Sheerness, and for this service the Lords of the Admiralty have granted the loan of two sailing ships, until recently laid up in ordinary at Chatham, namely, the Amethyst and the Iris. These ships have had to undergo very considerable alteration to render them suitable for the work, portions of the main deck having been removed—fore and aft—to make room for watertight tanks, which here, as elsewhere, are to be the medium for holding the cable. The Amethyst is now ready to receive cable, her two tanks being finished, and the hauling-gear and engine fitted on to her upper deck, ready for coiling it out of the factory. The Iris is in a forward state, and will be ready also in a few days. The dimensions of the two tanks on board the Amethyst are 29 feet diameter by 14 feet 6 inches in depth, and they will each hold 153 miles of cable: of those on the Iris, one will be 29 feet diameter and 14 feet 6 inches deep, and will hold 153 miles, and the other, which will hold 110 miles, will be 24 feet wide and 17 feet deep. The coiling on board the Amethyst will now commence in a few days, and the rate at which the cable can be taken on board her will be about two miles per hour to each tank.

The work on board the Great Eastern steamship is progressing very rapidly. She will contain three very large tanks, one situated in the forehold, one in the afterhold, and the third nearly amidships. The bottoms and the first tier of plates will be of five-eighths iron, and each tank, when completed to this height, is tested as to its tightness by filling it with water, and when found or made to be perfectly watertight, it is let down from its temporary supports on to a bed of Portland cement three inches in thickness, and the building up and riveting of the remaining tiers is continued. The beams beneath each tank are shored up from the floor beneath it down to the kelson with nine inches Baltic baulk timber; and it will give some idea of the magnitude of the work to state that upwards of 300 loads of this material are required for this purpose alone. The dimensions of the fore tank will be 51 feet 6 inches diameter by 20 feet 6 inches in depth, and its capacity is for 693 miles of cable. The middle tank will be 58 feet 6 inches broad, and 20 feet 6 inches deep, and it will hold 899 miles of cable, and the after tank will be 58 feet wide and 20 feet 6 inches deep, and will contain 898 miles. The three tanks are therefore capable of containing in all 2,490 miles of the new cable. The fore tank and the after tank are complete and tested, as high as the first tier of plates, and the erection of the remaining tiers is rapidly progressing. The space is cleared and shored up for the middle tank, and the laying of the iron floor has commenced. It is expected that the Great Eastern will begin to receive cable on board about the first week in January. Her deck engine and hauling-in gear are already prepared, and she will be able to get on board and coil the whole contents of the Iris or the Amethyst within three days from their arrival at Sheerness on each voyage.

The charge of laying the cable on the present occasion will be committed to Mr. Canning and Mr. Clifford, who, in concert with Sir Charles Bright, successfully submerged the original cable in 1858, and whose experience in this branch of engineering has been very large and varied. If all go well, the Great Eastern will be fully loaded and ready for sea by the end of June, 1865, and when fitted completely for this expedition, will have on board about 15,000 tons of cargo, of which the cable will be 4,500 tons, and the coals 8,000 tons; and her complement of hands all told, and including the electrical and engineering staff of the contractors, will be nearly 500 persons. Her commander has not yet been named, but it is to be hoped that no pains or expense will be spared to secure in him and his subordinate officers the very best men that the service can produce. Much will depend upon the manner in which the ship is handled, and as two vast enterprises will, on this occasion, be on their trial at one and the same time, a double responsibility will rest upon the officers to whom the conduct of this remarkable voyage shall be ultimately entrusted.

ON THE ELEMENTARY RELATIONS BETWEEN ELECTRICAL MEASUREMENTS.

By Professor J. Clerk Maxwell and Mr. Fleeming Jenkin.

II.

13. *Measurement of Electric Phenomena by their Electro-magnetic Effects.*—Before treating of electrical measurements, the exact meaning in which the words "quantity," "current," "electromotive force," and "resistance" are used will be explained. But in giving these explanations, we shall assume the reader to be acquainted with the meaning of such expressions as conductor, insulator, voltaic battery, &c.

14. *Meaning of the words "Electric Quantity."*—When two light conducting bodies are connected with the same pole of a voltaic battery, while the other pole is connected with the earth, they may be observed to repel one another. The two poles produce equal and similar effects. When the two bodies are connected with opposite poles, they attract one another. Bodies, when in a condition to exert this peculiar force one on the other, are said to be electrified, or charged with electricity. These words are mere names given to a peculiar condition of matter. If a piece of glass and a piece of resin are rubbed together, the glass will be found to be in the same condition as an insulated body connected with the copper pole of the battery, and the resin in the same condition as the body connected with the zinc pole of the battery. The former is said to be positively, and the latter negatively electrified. The propriety of this antithesis will soon appear. The force with which one electrified body acts on another, even at a constant distance, varies with different circumstances. When the force between the two bodies at a constant distance, and separated by air, is observed to increase, it is said to be due to an increase in the quantity of electricity; and the quantity at any spot is defined as proportional to the force with which it acts through air on some other constant quantity at a distance. If two bodies, charged each with a given quantity of electricity, are incorporated, the single body thus composed will be charged with the sum of the two quantities. It is this fact which justifies the use of the word "quantity."

Thus the quality in virtue of which a body exerts the peculiar force described is called electricity, and its quantity is measured (*cæteris paribus*) by measuring force.

The quantity thus defined produced on two similar balls similarly circumstanced, but connected with opposite poles of a voltaic battery, is equal, but opposite; so that the sum of these two equal and opposite quantities is zero; hence the conception of positive and negative quantities.

In speaking of a quantity of electricity, we need not conceive it as a separate thing, or entity distinct from ponderable matter, any more than in speaking of sound we conceive it as having a distinct existence. Still it is convenient to speak of the intensity or velocity of sound, to avoid tedious circumlocution; and quite similarly we may speak of electricity, without for a moment imagining that any real electric fluid exists.

The laws according to which the force described varies, as the shape of the conductors, their combinations, and their distances are varied, have been established by Coulomb, Poisson, Green, W. Thomson, and others. These will be found accurately described, independently of all hypothesis, in papers by Professor W. Thomson, published in the "Cambridge Mathematical Journal," vol. i. p. 75 (1846), and a series of papers in 1848 and 1849.

15. *Meaning of the words "Electric Current."*—When two balls charged by the opposite poles of a battery, with opposite and equal quantities of electricity, are joined by a conductor, they lose in a very short time their peculiar properties, and assume a neutral condition intermediate between the positive and negative states, exhibiting no electrical symptoms whatever, and hence described as unelectrified, or containing no electricity. But during the first moment of their junction, the conductor is found to possess certain new and peculiar properties: any one part of the conductor exerts a force upon any other part of the conductor; it exerts a force on any magnet in the neighbourhood; and if any part of the conductor be formed by one of those compound bodies called electrolytes, a certain portion of this body will be decomposed. These peculiar effects are said to be due to a current of electricity in the conductor. The positive quantity or excess is conceived as flowing into the deficiency caused by the negative quantity; so that the whole combination is reduced to the neutral condition. This neutral condition is similar to that of the earth where the experiment is tried. If the balls are continually recharged by the battery, and discharged or neutralized by the wire, a rapid succession of the so-called currents will be sent; and it is found that the force with which a magnet is deflected by this rapid succession of currents is proportional (*cæteris paribus*) to the quantity of electricity passed through the conductor or neutralized per second; it is also found that the amount of chemical action, measured by the weights of the bodies decomposed, is proportional to the same quantity. The currents just described are intermittent; but a wire or conductor, used simply to join the two poles of a battery, acquires permanently the same properties as when used to discharge the balls as above with great rapidity; and the greater the rapidity with which the balls are discharged, the more perfect the similarity of the condition of the wire in the two cases. The wire in the latter case is therefore said to convey a permanent current of electricity, the magnitude or strength of which is defined as proportional to the quantity conveyed per second. This definition is expressed by the equation

$$C = \frac{Q}{t}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where C is the current, Q the quantity, and t the time. A permanent current flowing through a wire may be measured by the force which it exerts on a magnet; the actual quantity it conveys may be obtained by comparing this force with the force exerted under otherwise similar conditions, when a known quantity is sent through the same wire by discharges. The strength of a permanent current is found at any one time to be equal in all parts of the conductor. Conductors conveying currents exert a peculiar force one upon another; and during their increase or decrease they produce currents in neighbouring conductors. Similar effects are produced as they approach or recede from neighbouring conductors. [illegible]

laws according to which currents act upon magnets and upon one another will be found in the writings of Ampère and Weber

16. *Meaning of the words "Electro-motive Force."*—Hitherto we have spoken simply of statical effects; but it is found that a current of electricity, as above defined, cannot exist without effecting work or its equivalent. Thus it either heats the conductor, or raises a weight, or magnetizes soft iron, or effects chemical decomposition; in fine, in some shape it effects work, and this work bears a definite relation to the current. Work done presupposes a force in action. The immediate force producing a current, or, in other words, causing the transfer of a certain quantity of electricity, is called an electro-motive force. This force is necessarily assumed as ultimately due to that part of a circuit where a "degradation" or consumption of energy takes place; thus we speak of the electro-motive force of the voltaic or thermo-electric couple; but the term is also used independently of the source of power to express the fact that, however caused, a certain force tending to do work by setting electricity in motion does, under certain circumstances, exist between two points of a conductor, or between two separate bodies. But equal quantities of electricity transferred in a given time do not necessarily or usually produce equal amounts of work; and the electro-motive force between two points, the proximate cause of the work, is defined as proportional to the amount of work done between those points when a given quantity of electricity is transferred from one point to another. Thus, if with equal currents in two distinct conductors the work done in the one is double that done in the second in the same time, the electro-motive force in the first case is said to be double that in the second; but if the work done in two circuits is found strictly proportional to the two currents, the electro-motive force acting on the two currents is said to be the same. Defined in this way, the electro-motive force of a voltaic battery is found to be constant so long as the materials of which it is formed remain in a similar or constant condition. The above definitions, in mathematical language, give $W = E\,C\,t$, or

$$E = \frac{W}{C\,t}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where E is the electro-motive force, and W the work done. Thus the electro-motive force producing a current in a conductor is equal to the ratio between the work done in the unit of time and the current effecting the work. This conception of the relations of work, electro-motive force, current, and quantity will be aided by the following analogy:—A quantity of electricity may be compared to a quantity or given mass of water; currents of water in pipes in which equal quantities passed each spot in equal times would then correspond to equal currents of electricity; electro-motive force would correspond to the head of water producing the current. Thus, if with two pipes conveying equal currents the head forcing the water through the first was double that forcing it through the second, the work done by the water in flowing through the first pipe would necessarily be twice that done by the water in the second pipe; but if twice as much water passed through the first pipe as passed through the second, the work done by water in the first pipe would again be doubled. This corresponds exactly with the increase of work done by the electrical current when the electro-motive force is doubled, and when the quantity is doubled.

Thus, to recapitulate, the quality of a battery or source of electricity, in virtue of which it tends to do work by the transfer of electricity from one point to another, is called its electro-motive force, and this force is measured by measuring the work done during the transfer of a given quantity of electricity between those points. The relations between electro-motive force and work were first fully explained in a paper by Professor W. Thomson on the application of the principle of mechanical effect to the measurement of electro-motive forces published in the "Philosophical Magazine" for December, 1851.

17. *Meaning of the words "Electric Resistance."*—It is found by experiment, that even when the electro-motive force between two points remains constant, so that the work done by the transfer of a given quantity of electricity remains constant, nevertheless, by modifying the material and form of the conductor, this transfer may be made to take place in very different times; or, in other words, currents of very different magnitudes are produced, and very different amounts of work are done, in the unit of time. The quality of the conductor in virtue of which it prevents the performance of more than a certain amount of work in a given time by a given electro-motive force is called its electrical resistance. The resistance of a conductor is therefore inversely proportional to the work done in it when a given electro-motive force is maintained between its two ends; and hence, by equation (5), it is inversely proportional to the currents which will then be produced in the respective conductors. But it is found by experiment that the current produced in any case in any one conductor is simply proportional to the electro-motive force between its ends; hence the ratio $\frac{E}{C}$ will be a constant quantity, to which the resistance as above defined must be proportional, and may with convenience be made equal; thus

$$R = \frac{E}{C}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

an equation expressing Ohm's law. In order to carry on the parallel with the pipes of water, the resistance overcome by the water must be of such nature that twice the quantity of water will flow through any one pipe when twice the head is applied. This would not be the result of a constant mechanical resistance, but of a resistance which increased in direct proportion to the speed of the current; thus the electrical resistance must not be looked on as analogous to a simple mechanical resistance, but rather to a coefficient by which the speed of the current must be multiplied to obtain the whole mechanical resistance. Thus, if the electrical resistance of a conductor be called R, the work, W, is not equal to $C\,R\,t$, but $C \times C\,R \times t$, or

$$W = C^2 R\,t^*, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where C may be looked on as analogous to a quantity moving at a certain speed, and C R as analogous to the mechanical resistance which it meets with in its progress, and which increases in direct proportion to the quantity conveyed in the unit of time.

18. *Measurement of Electric Currents by their Action on a Magnetic Needle.*—In 1820 Oersted discovered the action of an electric current upon a magnet at a distance, and one method of measurement may be based on this action. Let us suppose the current to be in the circumference of a vertical circle, so that in the upper part it runs from left to right. Then a magnet suspended in the centre of the circle will turn with the end which points to the north away from the observer. This may be taken as the simplest case, as every part of the circuit is at the same distance from the magnet, and tends to turn it the same way. The force is proportional to the moment of the magnet, to the strength of the current as defined by section 15, to its length, and inversely to the square of its distance from the magnet.

Let the moment of the magnet be $m\,l$; the strength of the current, C; the radius of the circle, k; the number of times the current passes round the circle, n; the angle between the axis of the magnet and the plane of the circle, θ; and the moment tending to turn the magnet, G; then

$$G = m\ C \, . \, 2\,\pi\,n\,k\,\frac{1}{k^2}\cos\theta, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

which will be unity if $m\,l$, C, k, and the length of the circuit be unity, and if $\theta = 0^{\circ}$.

The unit of current founded on this relation, and called the electro-magnetic unit, is therefore that current of which the unit of length placed along the circumference of a circle of unit radius produces a unit of magnetic force at the centre.

The usual way of measuring C, the strength of a current, is by making it describe a circle about a magnet, the plane of the circle being vertical and magnetic north and south. Thus, if H be the intensity of the horizontal component of terrestrial magnetism, and G the moment of this on the magnet, $G = m\,l\,H\sin\theta$, whence the strength of the current—

$$C = \frac{k^2}{2\,\pi\,n}\,H\tan\theta, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

where k is the radius of the circle, n the number of turns, H the intensity of the horizontal part of the earth's magnetic force as determined by the usual method, and θ the angle of deviation of the magnet suspended in the centre of the circle. As the strength of the current is proportional to the tangent of the angle θ, an instrument constructed on this plan is called a tangent galvanometer. The instrument called a sine galvanometer may also be used, provided the coil is circular. The equation is similar to that just given, substituting $\sin\theta$ for $\tan\theta$.

To find the dimensions of C, we must consider that what we observe is the force acting between a magnetic pole, m, and a current of given length, L, at a given distance, L_1, and that this force $= \frac{m\,C\,L}{L_1^2}$. Hence the dimensions of C, an electric current thus measured, are $\frac{L^{\frac{1}{2}}\,M^{\frac{1}{2}}}{T}$.

19. *Measurement of Electric Currents by their mutual action on one another.*—Hitherto we have spoken of the measurement of

* By equation (5) we have $W = C\,E\,t$; but by equation (6) $R = \frac{E}{C}$; hence $W = C^2 R\,t$.—Q.E.D.

currents as dependent on their action upon magnets; but this measurement in the same units can as simply be founded on their mutual action upon one another. Ampère has investigated the laws of mechanical action between conductors carrying currents. He has shown that the action of a small closed circuit at a distance is the same as that of a small magnet, provided the axis of the magnet be placed normal to the plane of the circuit, and the moment of the magnet be equal to the product of the current into the area of the circuit which it traverses.

Thus, let two small circuits, having areas A and A_1, be placed at a great distance, D, from each other in such a way that their planes are at right angles to each other, and that the line, D, is in the intersection of the planes. Now let currents C and C_1 circulate in these conductors; a force will act between them tending to make their planes parallel, and the direction of the currents opposite. The moment of this couple will be

$$G = \frac{A\,C \times A_1 C_1}{D^3} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

Hence the unit electric current conducted round two circuits of unit area in vertical planes at right angles to each other, one circuit being at a great distance, D, vertically above the other, will cause a couple to act between the circuits of a magnitude $\frac{1}{D^3}$. The definition of the unit current (identical with the unit founded on the relations given in section 18) might be founded on this action quite independently of the idea of magnetism.

20. *Weber's Electro-Dynamometer.*—The measurement described in the last paragraph is only accurate when D is very great, and therefore the moment to be measured very small. Hence it is better to make the experimental measurements in another form. For this purpose, let a length (l) of wire be made into a circular coil of radius, k; let a length (l_1) of wire be made into a coil of very much smaller radius, k_1. Let the second coil be hung in the centre of the first, the planes being vertical and at the angle θ Then, if a current C traverses both coils, the moment of the force tending to bring them parallel will be

$$G = \tfrac{1}{2} C^2 \frac{l l_1 k_1}{k^3} \sin\theta \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

This force may be measured in mechanical units by the angle through which it turns the suspended coil, the forces called into play by the mechanical arrangements of suspension being known from the construction of the instrument. Weber used a bifilar suspension, by which the weight of the smaller coil was used to resist the moment produced by the action of the currents.

21. *Comparison of the Electro-magnetic and Electro-chemical action of Currents.*—Currents of electricity, when passed through certain compound substances, decompose them; and it is found that, with any given substance, the weight of the body decomposed in a given time is proportional to the strength of the current as already defined with reference to its electro-magnetic effect. The voltameter is an apparatus of this kind, in which water is the substance decomposed. Special precautions have to be taken, in carrying this method of measurement into effect, to prevent variations in the resistance of the circuit, and consequently in the strength of the current.

22. *Magnetic Field near a Current.*—Since a current exerts a force on the pole of a magnet in its neighbourhood, it may be said to produce a magnetic field (section 6), and, by exploring this field with a magnet, we may draw lines of force and equipotential surfaces of the same nature as those already described for magnetic fields caused by the presence of magnets.

When the current is a straight line of indefinite length, like a telegraph wire, a magnetic pole in its neighbourhood is urged by a force tending to turn it round the wire, so that this force is at any point perpendicular to the plane passing through this point and the axis of the current.

The equipotential surfaces are therefore a series of planes passing through the axis of the current, and inclined at equal angles to each other. The number of these planes is $4\pi C$, where C is the strength of the current.

The lines of magnetic force are circles, having their centres in the axis of the current, and their planes perpendicular to it. The intensity of the magnetic force at a distance, k, from the current is the reciprocal of the distance between two equipotential surfaces, which shows the force to be $\frac{2C}{k}$.

The work done on a unit magnetic pole in going completely round the current is $4\pi C$, whatever the path which the pole describes.

AN ELECTRIC ANNUNCIATOR.

In a recent number of the *Scientific American* is published the following description of a new electric annunciator, from the pen of Mr. Thomas Taylor, of Washington. He says:—

"I was invited the other day by a friend to witness a few experiments in the telegraphing line, by means of a very simply-constructed device, and named by the inventor 'Electric Annunciator.' It is on private exhibition at the Smithsonian Institute, Washington, and was constructed and invented by Mr. John Blackie, recently of Scotland. The object of this invention is to enable the pilot of a vessel to communicate with the engineer or helmsman, whereby prompt and efficient orders may be transmitted. One most valuable feature of the device consists in the fact that every movement of the rudder is made known to the pilot or captain in their respective apartments, day or night. The Great Eastern was in the trough of the sea ten hours before the captain was aware that the shaft of the rudder was broken. The value of this instrument may be inferred from the fact that the annunciator would have informed him the moment the accident occurred; for it not only informs the pilot of the captain's wishes, but also communicates the pilot's orders to the engineer and helmsman. Further, it informs the captain whether his orders have been obeyed, the rudder itself giving the information by means of a different galvanometer. When the pilot sends an order he presses a knob and a bell rings, meaning attention. The engineer looks to the index, which resembles a clock face, on which are printed the five general orders used—viz., stop, a-head easy, a-head full speed, back easy, back full speed. The pointer indicates the order, and always remains at the last, and is locked. The device by which the pilot transmits his orders to the engineer is constructed as follows:—First, there is a dial on which the five orders described are printed. A pointer, like the hand of a clock, moves at the will of the pilot from order to order. The pointer is attached to a cylinder of iron four inches and a half long, half an inch diameter, which leads from the centre of the dial backward at right angles, and is supported at each end eccentrically. On each side are two electro-magnets, and one underneath, there being one magnet for each order. A wire from each magnet leads to the pilot-house, and all wires are connected with a battery. By means of five knobs in the pilot-house the connections are made, one on each wire. The iron cylinder or keeper moves from side to side, or downward, according to the attraction of the magnet, and as the pointer is attached to the keeper or cylinder, the movements on the dial will correspond with movements of the keeper, by reason of its eccentric motions. It is stated on good authority that four-fifths of the collisions on our rivers are caused by the present mode of signalizing by bells. The pilot rings to stop, and in an instant he may discover that he should proceed, and rings again, but the two orders are combined in one, and it may be forming one order in itself to the engineer, yet having no relation to the pilot's order, first or last. The prompt action of the engineer increases the confusion, and before it can be rectified a collision takes place. Our late sea fights at Mobile will suggest to any one the necessity of some brief yet more perfect mode of conveying positive information between the commander, pilot, and engineer than ringing a bell. One false move may be the destruction of many lives and much property, and cause terrible disaster to the nation.

"I shall now describe the mode of arrangement by which the captain or pilot may understand the movements of the rudder while in their respective departments. I shall first describe the arrangement of wires, &c., then the mode of attaining results. From the battery to the rudder head a wire is led. From the rudder head to the cabin two wires are led, and from thence to the battery one wire is led and connected. I shall now describe the arrangements in the cabin. Each of the two wires mentioned terminates in a coil, but they are wound up in opposite directions; each coil is placed on the top of the other, and in contact (insulating wire is used), the two ends are left out, and connected here with the third wire which leads to the battery. The coil is of oval form, about four inches and a half long, and two inches wide. A magnetized needle is suspended in the centre; a dial is also used, to which the needle points. This combination forms a differential galvanometer. I shall now describe the combination at the rudder head. A coil of wire like a bell spring, say six inches long and three-eighths of an inch in diameter, connects the two wires alluded to previously, which lead to the cabin. The third wire is connected to a roller which rests on the coil at right angles to it, but this roller is connected with the rudder head in such a manner, that when the

rudder moves from side to side, the roller will move from end to end of the coil, and in contact. The only use of the wire being in coil form is to have a long piece of wire in a short compass. This completes the arrangements. The battery being in action, a current will pass from the battery to the rudder head, conducted by the roller to the coil. If the roller is in the centre the current will split, and one-half go by each wire to the cabin, and as the two coils are wound up in different directions, one current will traverse in one direction and the other in another, but of equal strength. The needle, therefore, will stand perpendicularly. But should the roller move to one end of the coil by a movement of the rudder, the greater part of the current will take the shorter route, and the needle will be deflected, say to the right. A movement to the other end of the coil will cause a deflection to the left for the like reason. It will at once be seen that intermediate movements on the coil will cause corresponding movements of the needle. Thus every movement of the galvanometer indicates every movement of the rudder."

From the foregoing description we are led to conclude that this instrument is very similar in character to Gisborne's ship-steering telegraph.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XIX.

A.D. 1842, November 25.—No. 9528.—Talbot, William Henry Fox.—"Improvements in coating or covering metals with other metals," consisting of:—1st. Preparing metallic surfaces for gilding, by means of a very thin coating of silver, given by immersion in a weak solution of silver in hyposulphite of soda. 2nd. Preparing metallic surfaces for gilding or silvering, by attaching the well-cleaned article "to one of the poles" of a voltaic battery, and plunging both the poles into an acid or saline solution, so as to cause the surface to be gilt to give off hydrogen freely; the article is then "immediately thrown" into a proper solution of gold or silver, and is thereby coated; it is then washed. The process is repeated as often as may be necessary. 3rd. Gilding metallic articles by immersion in a mixed solution containing chloride of gold, mixed with nitrate of lead or hydriodate of zinc. A weak solution of gold is used first, then a strong solution. 4th. "Using a solution of chloride of gold, mixed with a solution of boracic acid, for the purpose of gilding articles of brass or other metal." 5th. When metallic articles "acquire a dark tint," by being dipped into a solution of gold, dipping them into a weak solution of nitrate of mercury, then again into a solution of gold, and so on. The excess of mercury may be removed by an acid, "assisted by voltaic action." 6th. Silvering metallic articles by immersion in different solutions, thus making the metal on the surface become dissimilar to that in solution. A different solution of silver, or of some other metal, may be used. A slight coating is given by voltaic action, "and these dippings are then to be repeated alternately." This method applies to gilding also. "Brass, copper, silver, German silver, iron, and steel," may be coated by the processes described in this specification.

A.D 1842, December 28.—No. 9572.—Hull, Alonzo Grandison.—"Improvements in electrical apparatus for medical purposes, and in the application thereof to the same purposes." The mode in which these improvements are carried into effect is as follows:—"1st. By "making the opposite poles of the electrical circuit of different sizes for the purpose of regulating the quantity, intensity, or quality of the electrical force." 2nd. By "the introduction of medicine into the electrical circuit." 3rd. By "insulated conducting wires for passing the electric current into particular parts of the body." 4th. By "putting particular parts of the body into a positive or negative state of electricity, in order to stimulate, or dissolve, or form it anew." 5th. By "varying the extents of the conducting surfaces, and quantity of water or other fluid, or kind of fluid, or medicine, for the purpose of modifying the electric current." 6th. By "introducing medicine into the body by means of immersion or partial immersion in a bath acted upon by an electrical apparatus." The other points alluded to in the specification are explanatory of the above, and refer also to varying the "conducting power of the water or other media in contact with either pole," also to water or other fluid or medicines or other media," being "the communicating medium between either one or both of the poles and the animal body," and to other means of modifying and applying electrical apparatus to medical purposes.

A.D. 1843, February 21.—No. 9641.—Blackwell, Benjamin Brunton, and Norris, William.—The title of this invention is as follows:—"An improvement in coating iron nails, screws, nuts, bolts, and other articles made of iron with other metals;" and the invention relates to coating iron with copper by galvanic agency. The improvement consists in rendering the iron surface "much less electro-positive to copper, less liable to oxidation, and in a better state for receiving a sound, firm, and ductile coating of copper," either by case-hardening the articles of iron, or by previously coating them with lead or an alloy of lead. The articles may be case-hardened by subjecting them to a red heat in a crucible or iron box, in contact with parings of hoof or horn, or bone dust; the case-hardened surface should be thin, otherwise small articles are liable to be brittle. Articles are coated with lead or its alloys by immersion in the molten metal "in precisely the same manner as is known and practised for covering iron with tin." The alloys of lead that may be used are, lead and tin, and lead, tin, and antimony. The iron goods may be placed (whilst hot from the preparatory process) in a solution of copper, in the galvanic circuit, the battery being kept at 80° or 100° of Fahrenheit's thermometer.

A.D. 1843, April 11.—No. 9698.—Napier, James.—"Preparing and treating fabrics made of fibrous materials," by the electro-deposition of "metal or metals" upon them, so as to make them applicable to "covering roofs," "the bottoms of ships," and other useful purposes. The electric current may be "derived from a galvanic battery or any other source." The invention is described under two heads:—1st. "The preparation of the fabric so as to give it a conducting surface." Any convenient method may be employed; the following methods are described:—The fabric is immersed, and sometimes boiled, in an agitated mixture of plumbago, ground very fine, and water. A pulverized "compound of zinc and iron," mixed with black lead, "is very useful in obtaining a metallic surface." Or "plates or other convenient pieces of metal" are "closely attached to the opposite side of the fabric." Or the fabric is impregnated "with a salt of copper," and glycerine used to reduce such salt. Or the impregnated fabric is exposed to "a current of phosphoretted" [phosphuretted?] "hydrogen and other gases," in a mode described. "Phosphorus dissolved in sulphuret of carbon," "diluted with turpentine," is a reducing agent to be applied to the impregnated fabric "after having been first dipped in the solution of phosphorus." The introduction of "thin metallic wires at intervals into the fabric," is "a method of producing a stronger bond of union between the fabric and the metal." 2nd. The mode of electro-depositing "on fibrous materials." In a vessel containing the depositing solution is placed several sheets of iron, covered on one side with a diaphragm of plaster of Paris and Roman cement, and on the other with the fabric to be deposited on; the whole are then connected by suitable wires so as to form "a galvanic series;" a galvanic battery may be interposed beween the poles to assist the action. Another mode is, to attach the fabric closely to a plate of metal, so as to surround it; paste may be used for this purpose, and the face of the fabric made well conducting; or the fabric may be pasted on to a plate of amalgamated zinc, and the compound of zinc and iron rubbed upon the surface; this is then "placed in a suitable metallic solution," connected properly with a galvanic battery, and the electro-deposition conducted in the usual manner. Or the fabric may be electro-coated in the usual manner, after having its surface made conductable.

A.D. 1843, May 25.—No. 9741.—Pool, Moses (*a communica o*—"Improvements in the deposition of certain metals, and in apparatus connected therewith," consisting "in the employment of certain solutions of gold, silver, and copper," and in the "application of a thermo-electrical battery or apparatus in connection with the same," or other solutions. Silver solution is made by dissolving carbonate of silver (precipitated from the nitrate by carbonate of soda) in a solution of hyposulphite of soda or potash and carbonate of soda; hyposulphite of soda or potash, and carbonate of soda, should be added, so that the solution may contain those salts in the free state. Or, the above solution is boiled "for one hour: during which time a portion of silver is precipitated and the hyposulphite changes, forming a new and distinct salt." Gold solution is made by precipitating "the gold" by "liquor ammoniac" from a solution of gold in nitro-muriatic acid, evaporated "until it assumes a deep red colour," and then diluted: "this precipitate of gold" is dissolved in a solution of "hyposulphite of soda (or potash)" by boiling. Copper solution is made by dissolving car-

bonate of copper in a solution of "hyposulphite of soda (or potash)," and carbonate of soda. The above solutions are used "with currents of electricity." The "thermo-electrical battery" consists of 100 pairs of German silver and iron rods connected together alternately, and placed (insulated from each other) upright in an iron vessel by means of plaster of Paris or clay, but so that all the soldered parts of the series are uncovered. The upper surface is covered with pitch, and has a current of cold water flowing over it; the iron vessel or "frame" is so placed that the lower ends of the series dip into a sand bath "heated nearly to redness." A battery of fifty pairs might suffice for small articles.

A.D. 1843, May 27.—No. 9745.—Bain, Alexander.—"Certain improvements in producing and regulating electric currents, and improvements in electric timepieces, and in electric printing and signal telegraphs," relating to:—1st. "The production of electric currents" by means of one or more positive and negative "substances placed in the earth, or in "natural bodies of water," proper insulated metallic connections being used. 2nd. Regulating voltaic currents. By means of a sliding spindle carrying a pin, the keeper of an adjustable electro-magnet, included in the circuit, stops a clock mechanism, to which the battery plates are attached as a weight whilst the current is sufficiently strong; but when the current weakens, a spring forces the keeper back, and the plates are let down into the solution. Another arrangement:—The plates merely act as the weights to a clock. A third arrangement:—When the current weakens, solution is admitted to the battery by means of a lever and stopper attached to the keeper of an electro-magnet included in the circuit. 3rd. Improvements applied to timepieces and printing or signal telegraphs. Various arrangements, on which the improvements depend, are first set forth; they are as follows:—A rectangular coil of insulated wire is suspended, free to vibrate, between the poles of a permanent horseshoe magnet, or of two horseshoe magnets with opposite poles facing each other, the axis of the coil being at right angles to the axis of the magnet; motion of the coil is produced by the reversal of the direction of the electric current. In another pendulum arrangement, the axis of the coil is parallel to the axis of the magnet; in this case similar poles face each other when two magnets are used. In a third pendulum arrangement, the permanent magnet has a central south pole surrounded by a number of north poles; two magnets, with similar poles facing, may be used. In a fourth arrangement, "a permanent magnet, suspended compass fashion," has two segmental arms free to move through the centres of two coils according to the direction of the electric current; or two semicircular magnets, with similar poles facing, fixed to a brass bar, may be used. The above arrangements are applied to electric clocks in the following manner:—Separate pendulums regulate each other by the third arrangement. The coil is mounted on a spring, and has a catch (included in the circuit) which detains each pendulum until the last has completed the circuit, and enabled the coil to enter the hollow magnet. In another application, a pendulum is worked by means of the first arrangement, one wire being attached to the point of suspension, the other to the axis of an arm carrying a ball on the pendulum, which, by falling from side to side during the vibration of the pendulum, completes and breaks the circuit at proper intervals. In a third application, a pendulum, vibrating according to the third arrangement, is used with the arm and ball movement, the coiled pendulum bob being attracted whenever the circuit is completed through the ball, but not otherwise; in this case the vibration of the pendulum works the clock by means of a click spring and click wheel, or it merely works the escapement, as may be required. A method of working a set of clocks without breaking the main circuit, by a branch circuit returning into the main wire, is set forth. The applications of the electro-magnetic arrangements to printing telegraphs are as follows:—The third arrangement is used to stop governor balls connected with signal and printing apparatus, the current always passing through the coil, except when a signal is made. When the governor balls rotate, they enable one spring barrel to rotate the signal pointer and type wheel, until the hands of both the telegraph instruments (which are alike) point to the desired signal, when another spring barrel is permitted to act on the printing apparatus by means of the governor lever and pallets. The printing apparatus consists of a crank and levers, which move the type wheel up to the paper and the paper roller on its fixed screw axis, by means of a click, click wheel, long pinion, and spur wheel; a blackened ribbon is used to make the characters visible; the dials of both instruments contain ivory studs, which assist their action, and enable the instruments to be adjusted. It is proposed to lay the long conducting wires in grooves (filled with asphalt), in wood pavement, or railway sleepers. A method of "taking copies of surfaces, for instance, the surface of printers' types, at distant places," is described and shown. Somewhat similar apparatus is used at each station; two pendulums regulate each other by the first method herein described in relation to electric clocks, and complete the electric circuit through short insulated wires in a frame in contact with printers' type at the telegraphing station; at the receiving station, the type is copied by the wires, in a series of small dots, on paper moistened with prussiate of potash and nitrate of soda; the type and moistened paper are lowered alike by the action of the electric current in connection with clockwork. A signal telegraph is described and shown, in which the hand points to I or V according to the direction of the current, and is moved by two semicircular magnets, as in the fourth electro-magnetic arrangement. A method of conveying intelligence to police or fire stations is also described and shown. By clockwork, inlaid metal wheels complete and break a circuit the requisite number of times, thus causing a hand at the other stations to indicate the number of the station by the last method herein described in relation to electric clocks.

A.D. 1843, June 15.—No. 9786.—Barratt, Oglethorpe Wakelin.—"Certain improvement in gilding, plating, and coating various metallic surfaces," relating:—

To a voltaic battery for "the deposition of metals," consisting of lead, carbon, and solution of chloride of sodium. "The products of the battery are chloride of lead and caustic soda mixed with carbonate of soda, the value of which products is considerably greater than the expense incurred in the deposition of the metal."

To another battery for the deposition of metals, consisting of zinc, carbon, and water. Fifty cells are recommended for gilding and silvering, and plumbago crucibles may be used as negative plates.

To "obtaining electricity continuously from the magnet" for the deposition of metals. "An electrical-magnetic battery, or battery of magnets," is made by fixing firmly in wood any number of magnets, and forming a continuous metallic circuit, by connecting opposite magnetic poles by means of iron wire. The north pole of the first magnet must be connected with the work to be coated by a copper wire, and the south pole of the last magnet is connected to the dissolving plate by an iron wire. Rotary motion is not required in this arrangement to evolve electricity.

To "the dissolving of the metals." An aqueous solution of "nitrate of potash, chloride of sodium, and sulphate of alumina and potash," is made, and the metal is dissolved in it by suitable battery arrangements until a proper deposit is obtained. The other solvent solutions that may be used are:—For silver, "chloride of sodium or hyposulphite of soda, or cyanide of potassium;" for "gold, platinum, lead, silver, paladium, and other metals," chloride of sodium and boracic acid, or chloride of sodium and tartaric acid.

A.D. 1843, October 27.—No. 9917.—Hull, Alonzo Grandison.—"Improvements in manufacturing or improving fermented and distilled liquors." These consist in "passing a current of electricity through a current of wine, spirits, beer, or other fermented or distilled liquors by means of an electrical apparatus," in order to improve the quality of the liquor so operated upon by perfecting the fermentation, and thereby giving to the liquor a property similar to that usually acquired by age, and likewise affording a means of separating the acetous part of the liquor from the general mass." A method of effecting this object is given by "inserting the poles of a galvanic battery into the liquor;" the kind of battery to be used, the time of its action on the liquor, and the disposal and size of the poles, are set forth. "The most acid condition of the liquor will always be at the positive pole, and from which any quantity may be drawn in case the acid should be too redundant to be mixed up with the mass."

A.D. 1843, November 9.—No. 9932.—Bush, William.—"Improvements in rendering magnetic needles less prejudicially influenced by local attraction," consisting of "a mode of constructing a marine compass, whereby the local attraction may be centralized in or near the axis of motion of the magnetic needle." The compass bowl has fixed to its under part vertical magnetic bars, "chain, tubes, or other forms of steel or iron, supported by an universal joint;" they "act as a pendulum and conductor," and receive "the magnetism of all the iron which might surround" them. Either a single bar may be placed with either pole uppermost, or tubular magnets may be disposed concentrically with alternate poles uppermost, there being a space between. The outer tubular magnet or collection of magnets are shown concentric with

the needle centre in plan, and the outer casing of these vertical magnetic bars is of brass "to protect the magnetic bars or tubes from corrosion." "Where the barometer is required" the middle magnetic bar "may be removed, "and mercury substituted;" in this case there is a "magnetised steel or iron cistern, connected with the magnetic tube, through which the mercury will ascend, serving also as a balance for the bowl or basin which is supported by it." Magnetic needles are described and shown, with 8, 6, and 4 points, respectively having 4, 3, and 2 similar poles, also one needle with two north poles and one south pole. In this invention the bowl contains a cistern of mercury, in which the "axis of the compass" floats by means of a "float or cork." A hollow cone is "placed under the needle; this cone on its under slide" [side?] "has an agate to receive the upper end of the axis affixed on the float, and on its upper surface it has another agate to receive the lower end of the point," "of the needle; and in case the cone is not used, then the axis affixed in the float receives the magnetic needle, it being provided with a suitable agate to receive the point of the axis."

CORRESPONDENCE.

A HOLIDAY FOR TELEGRAPH CLERKS AT CHRISTMAS TIME.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—Will you kindly use your valuable influence in behalf of the female telegraph clerks of London for a holiday at Christmas? I do not think it at all likely we can get a whole holiday on the Monday, but do think our managers might allow us to close at two o'clock on the Saturday (Christmas Eve), and so give a great many of us the pleasure of helping to make, as well as to eat, our Christmas pudding.—I am, Sir, yours, &c.,

Dec. 12. MARIA ELLINGTON.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir,—I know you are always ready to lend a helping hand when the good of telegraphers is in question, and therefore invite the aid of your valuable journal in obtaining a holiday for a large number of your readers on the Monday following Christmas Day. If our directors will take time by the forelock, they could give due notice that their offices will be closed on the 26th instant from a certain hour in the morning, and no greater difficulties need be apprehended than those experienced by persons who have need of the telegraph on Sunday.

A large number of places of business in the city will suspend operations from Saturday, the 24th instant, at 2 P.M., until Tuesday, the 27th instant. We cannot expect (as servants of the public) so grand a concession as this; but I sincerely hope that our directors will contrive to let us have a few hours with our friends at Christmas-tide.—Believe me to be, &c.,

Telegraph-street, E.C., 13th Dec., 1864. A MORSE CLERK.

To the Editor of the TELEGRAPHIC JOURNAL.

Sir.—Permit me, through the medium of your columns, to invite the attention of directors and managers of telegraph companies to the circumstance that Christmas-day this year falls on a Sunday. Most telegraph clerks enjoy the privilege of one day's rest in seven, and on the occasion in question will sacrifice the holiday for the orderly observance of the holy day. I (speaking for others as well as myself) venture to think that if the managers of the several large telegraph establishments in large towns cannot dispense with the services of the whole of their staffs on Monday, the 26th instant (the day on which the festivities of the season will be most generally indulged this year) that at any rate they could give us a little opportunity for participating in the joys and pleasures of Christmas time by granting a half holiday to a moiety of the establishments on the 24th instant, and a half holiday to the other moiety on the 26th instant.

I am fearful of trespassing too much upon your valuable space, so I will conclude by urging on behalf of this little appeal that "Christmas comes but once a year."—I am, &c,

14th December, 1864. YULE LOG.

CONSTANCY OF DANIELL'S BATTERY.—In order to increase still more the constancy of the Daniell's battery, Father Secchi advises the use of fine sand or of powdered sulphur in the porous cell. He accounts for its action by supposing that when the ordinary liquid alone is used there is greater liability to local action taking place upon the zinc. In a battery, the circuit of which is closed for two minutes every quarter of an hour, the learned Father has used an ordinary piece of commercial sheet zinc, half a millimetre in thickness, which has continued in action for more than six months, without showing the least sign of corrosion. For large elements, instead of porous diaphragms, he uses bags made of course linen cloth, well anointed with a luting of flour and lime. Those who have experienced the difficulty of procuring large porous cells would do well to test these contrivances.

TELEGRAPHIC NEWS.

ELECTRIC TELEGRAPH BETWEEN GREECE AND THE IONIAN ISLANDS.—Our Paris correspondent informs us that a convention has been concluded between the Hellenic Government and Messrs. Newall & Co., of Gateshead-on-Tyne, for the establishment of a line of telegraph to connect Greece and the Ionian Islands.

TELEGRAPH TO INDIA.—By a telegram, received through Mr. Reuter's agency, dated Constantinople, December 9th, we are informed that a convention has been signed between the Porte and Persia for an Indian telegraph line *viâ* Panakian (?) pending the completion of the line to Divanich (?). The service will soon open.

A NEW SUBMARINE CABLE.—A correspondent of the *New Orleans Times*, writing from Fort Gaines on the 29th September, says:—"There is now a fine submarine telegraph cable working between this place and Fort Morgan. It is a good thing, as it lessens the duty of the signal corps, who until recently have had a hard time of it."

FIRE AT A TELEGRAPH WORKS.—On the 9th instant a fire broke out on the premises of Messrs. Reid Brothers, telegraph engineers, Wharf-road, City-road. The fire was discovered by the policeman on duty at the time, who quickly summoned the brigade; and, as a plentiful supply of water was at hand, the flames were confined to the engine-room, the locality in which the fire originated. We are glad to be able to state that business will be carried on as usual by the firm. The damage is fully covered by insurance.

EXTENSION OF THE PNEUMATIC DISPATCH AND TELEGRAPHIC SYSTEMS IN LONDON.—On the 13th instant the entire road traffic between Chancery-lane and the top of Gray's-inn-lane was stopped and diverted round by King's-road and Hatton-garden on the one hand, and Chancery-lane and Castle-street, Holborn, on the other, to enable the contractors and their workmen to excavate the roadway for the laying down of the pneumatic tubes, in continuation of the line from Euston-square. The operations for this purpose are being carried on day and night, with a view to the proposed completion of the line and its opening for traffic to the Post-office before the end of January. The requisite Parliamentary powers having been obtained last Session, it is not intended to wait, as was at first thought desirable, for the construction of the Holborn-valley viaduct, by which means the pneumatic tube would have been carried continuously on a level, but to sink the tube under the Valley from Holborn to Snow-hill, it being perfectly practicable by the atmospheric system to work any ordinary load up or down these inclines. From Snow-hill the line will pass under Newgate-street into the Post-office yard, in St. Martin's-le-Grand, where the city station will be established, the site having been granted by the Post-office authorities. The works will be carried forward with as much rapidity as possible, so that the public traffic may be interfered with and suspended as little as possible. Telegraphic wires are to be laid down simultaneously with the tube, for its safe working from terminus to terminus, and there is to be an intermediate station adjacent to the Inns of Court Hotel, now constructing in Holborn.

ELECTRIC AND INTERNATIONAL DRAMATIC CLUB.—On Thursday evening last a private entertainment was given at the Cabinet Theatre, Liverpool-street, King's-cross, by the members of the above club. The theatre was well filled by the friends of the society. The performance commenced with a *petite* comedy, by C. Dance, Esq, entitled *Advice Gratis.* (Mr. Odbody) Mr. F. Perry; (Mr. Eventide) Mr. F. Tranfield; (Edmund) Mr. J. Pike; (Grimes) Mr. J. Hodges; (Mrs. Eventide) Miss Grosvenor; (Ellen) Miss Annette Hall. This *morceau* was followed by the laughable farce, by T. W. Morton, Esq., of *Done on Both Sides.* (Mr. Whiffles) Mr. F. Perry; (Mr. Brownjohn) Mr. R. J. Garrard; (Mr. Pygmalion Phibbs) Mr. W. Coleman; (Mrs. Whiffles) Mrs. Malcolm; (Lydia Whiffles) Miss Annette Hall. The entertainment concluded with the musical farce, by E. Blanchard, Esq., of *The Artful Dodge.* (Mr. Gregory Grudge) Mr. F. Tranfield; (Timotheus Trundle) Mr. W. Simmons; (Tom Toddle) Mr. Jackson; (The Honourable Fredrick Flamwell Fitz-Fudge) Mr. R. J. Garrard; (Demosthenes Dodge, Esq.) Mr. W. Coleman; (Nudge) Mr. Prest; (Budge) Mr. P. Ellis; (Emily Wilton) Mrs. Malcolm; (Susan Smudge) Miss Grosvenor. It would be invidious to select any of the performers for special commendation, as each character was well sustained. The ladies acted their parts with uncommon grace and confidence. Appearances go a great way now-a-days; and it will be but an act of justice to the fair artistes if we express our conviction that the *costumier* in dressing the pieces sadly neglected his art. Of the most conspicuous characters we may mention that Messrs. Garrard, Coleman, and Perry, elicited warm applause by their several delineations, although it was evident throughout that the pieces had been put upon the stage without sufficient rehearsal.

TELEGRAPHIC GRIEVANCES.—The following letter, complaining of the manner in which the telegraph service between India and England, *viâ* Italy, is conducted, appeared in the columns of the *Times* on the 13th instant:—"London, Dec 12.—Sir,—We inclose copy of telegram as received from India, the 28th ult., addressed to us at 'French Wool-street.' On applying at the office of the Submarine Telegraph Company we were informed that the Italian Government some time ago had discharged their English clerks, and have since been obliged to forbid repetitions, as there were so many required that their lines were quite 'blocked up' with them. We had hopes held out that ours should be an exception, but we have

waited a fortnight without hearing further. We should mention the message is not a cypher. As it is right that the public should know in what manner and under what conditions this important service is carried on, we take the liberty of infringing on your valuable space with a specimen.—We are, Sir, yours obediently, 'H.':—'Thro following giving and deare Servie giving and clewie ware coming to the trial master come his presence indispensable no other oath but to would avail against." Another correspondent writing the *Times* on the 14th instant, observes:—"We have received the following notice from the Submarine Telegraph Company—'Notice, if a receiver of a message has reason to suppose that his message has been incorrectly transmitted, and on that or any other account desires a repetition of it, the company is reluctantly obliged to give notice that, for the future, in conformity with a regulation of the Continental telegraph administrations, he will be required to pay for another message and reply. S. M. Clare, Secretary, 58, Threadneedle-street, London, E.C., Nov., 1864.' We pay annually a very large sum of money to and from Alexandria, and rarely receive one correctly transmitted; and often those received are so unintelligible that we are obliged to apply for a repetition before we can act. It seems that we are now, in addition to the loss and annoyance above stated, to pay for the correction of errors caused by the wrong transmission of our messages by the telegraph clerks. We have lost thousands by delay in the transmission of messages and by the incorrectness of those transmitted, and as we know many are in the same position, we beg to say that we will gladly combine with other respectable firms in testing the liability of the companies regarding these irregularities, and by so doing try to secure something like value for our money.—Yours very truly, Charles Leigh Clare & Co., 1, Mount-street, Manchester."

Russian Telegraphs.—The following description of the actual and prospective arrangements of Russia for the general extension of telegraphic communication, and especially as regards the reported project for a line across Behring's Straits, is from the *London and China Telegraph*:—"From St. Petersburg we learn that Mr. Collins has arrived there from America to negotiate with the Russian Government on the telegraph to connect the two hemispheres. According to the despatch addressed by Mr. Secretary Seward to Mr. Collins, and the project laid before the Congress of the United States, a line of telegraphs is to be constructed from some point in the North-Western States of the Union, or their territory on the Pacific, through British Columbia and the Russian-American possessions, thence by a submarine cable of only thirty miles under Behring's Straits, from Cape Prince of Wales to Cape East, the extreme point of the Asiatic Continent. From this spot it is to be continued by a submarine line under the Gulf of Anadir, thence by land across the neck of the Peninsula of Kamtschatka and round the shores of the sea of Ochotsk to the mouth of the Amoor to join the great Russian line of communication with St. Petersburg, and thence with the whole of Europe. Partly to correct some mistakes in Mr. Seward's despatch, and partly to rectify some false impressions that have got abroad, the Russian Telegraph Department has just published an official account of the present state of the works. From this it appears that the line from St. Petersburg is open as far as Irkutzk, the seat of Government in Siberia, whence wires have just been put up, and are opened to Kiachta, the last Russian town, close to the frontiers of China. From this point the telegraph will be eventually carried on to the town of Ourga, and thence through Mongolia and the Great Desert of Gobi to Pekin, terminating at Tien-tsin, on the Gulf of Betchili. 'But,' says the report, 'when this extension will be carried into execution is not yet officially decided.' On the other hand, a line hitherto intended for the exclusive use of the Naval Department is being constructed along the right bank of the Amoor, from Charabofka to Nicolayefsk, to be continued by-and-bye up the Ussouri, and thence to the Gulf of Possiet, in the Sea of Japan. In the concession applied for by Mr. Collins, but not yet granted, the Russian Government is required to construct the line from Wershne-Udinsk to a point on the Amoor, to meet the American line. This comprises a distance of 3,000 versts, or 2,000 English miles, and its execution on the part of Russia is made dependent on the funds being subscribed in America, so as to ensure the performance of their part of the contract within a given period of time, to be fixed by mutual consent. Mr. Seward's statement that this line has been commenced, and is going on with activity, appears, therefore, to be erroneous. A long time will probably intervene before the projected telegraphic communication between the Old World and America can be completed by way of Behring's Straits, and if the new Atlantic telegraph cable be successfully laid in the spring, Mr. Collins's plan will be superfluous, and probably fall to the ground."

Telegraphic Lines in Turkey.—The announcement recently published that the Anglo-Indian telegraphic service through Turkey was now in a complete state is anything but correct, notwithstanding that the convention for its working has been signed. I have already informed you of the inefficiency of the whole system, and since that report matters have gone on from bad to worse up to the present moment, when they may be said to be in a deplorable state. As a proof of this I have only to cite the fact of the gross irregularity with which telegrams from this city reach London, and, even when received, the imperfect manner in which they are transmitted. The reason for this is obvious, and may be very briefly stated. In the first place, the Turkish European lines have been allowed to fall into such a defective condition that they now stand in need of thorough repair, which the Administration, with a very erroneous idea of economy, hesitate to undertake; and, in the next place, notwithstanding the strong remonstrance of the director of the European service, all the employés with any experience have been transferred from the European stations, and removed to the Asiatic line, to meet what is expected to be the increased traffic of the new Indian service. As a natural consequence, the inefficiency of the new hands, coupled with the defective state of the wires, renders the communication with Europe as bad as it possibly can be, and holds out anything but an encouraging prospect for the future regularity of our Anglo-Indian telegraphic correspondence. The real source of this unsatisfactory state of things is to be found in the practice of constantly changing the director-general of the service. I have already pointed this out, and alluded to the powerlessness of the then occupant of the post, Debran Bey. He has since been removed, and his place supplied by Agathon Effendi, who appears to be just as much impressed with the insecurity of his position as his predecessor, and consequently does little or nothing towards bringing about any change for the better. The chief of the Anglo-Indian telegraph, Colonel P. Stewart, who has been zealously engaged here for some time past in trying to put matters in proper train, appears to have been thoroughly disgusted with the immense difficulties he has to contend with, and is now laid up seriously ill. He has been very efficiently supported by Lieutenant-Colonel Golsmith and the resident agent for the Indian Government, Mr. W. L. Courteney. All their exertions, however, to put the telegraphic communication on a satisfactory basis must prove of little avail if they cannot succeed in obtaining a radical reform in the Ottoman telegraph administration, or, in the absence of that, in employing experienced persons enough to see that proper steps are taken to ensure something like regularity in the transmission of messages. It is a fact of the utmost importance, and should be made known, that Russia has now for some time had telegraphic communication with India. A Russian line passes direct to Teheran, and from thence there is a line communicating with the Persian Gulf submarine cable. Of course it would be impracticable to make use of this means of sending messages for our Governmental service, but for commercial purposes it might to a certain extent be employed. Whether this may be so or not, the circumstance of Russia having this line at her command is suggestive of serious consideration, and cannot fail to attract attention.—Correspondent of the *Daily Telegraph*.

MISCELLANEA.

The Telegraph Operator.—A man who lives almost exclusively on *tick*.

Preservation of Wood.—The following method is used in Germany for the preservation of wood:—Mix 40 parts of chalk, 40 of resin, 4 of linseed oil, melting them together in an iron pot; then add one part of native oxide of copper, and afterwards with care, 1 part of sulphuric acid. The mixture is applied while hot to the wood by means of a brush, when dry it forms a varnish hard as stone. This method would be extremely applicable to the preservation of telegraph poles, and other wood-work exposed to the destructive influences of air and water.

The Preservation of Iron in Water.—At the last sitting of the Academy of Sciences, M. Becquerel read a paper on the preservation of cast-iron and iron in fresh water. He had previously shown that when a plate of either material was in contact with a zinc plate, not exceeding the 100th part of the surface of the former, the intensity of the derived electrical currents on the protected metal would in sea water diminish as the distance from the point of contact of the two metals increased, but nevertheless so that the protection afforded by these derived currents would still extend to a considerable distance from the said point of contact. In fresh water there are fewer divided currents on the surface of the metal, a fact which M. Becquerel attributes to the difference of conductibility of the two liquids, and the degree of chemical action which each exercises on the zinc.

The Theory of Expansion.—The very first approximate results of Mr. Fairbairn's experiments showed a wide departure from the Marriotte law. Mr. Fairbairn gives the following table of the density of steam at various temperatures as computed from the old formula and as determined by his own observations. The density is stated in the number of times which the volume of steam is greater than the volume of the water from which it was formed:—

Temperature.	Volume of Steam. By Formula.	Volume of Steam. By Experiment.
244°	1,005	896
245°	969	890
257°	790	651
262°	740	640
268°	680	633
270°	660	604
283°	540	490

These experiments of Mr. Fairbairn overthrew the old notions in regard to the density of steam when formed at different pressures, and they determined the real facts in regard to this branch of the subject, but they by no means settled the question of expansion. Steam formed at a temperature of 283° has a volume 490° greater than the water from which it was formed, while steam at 244° has a relative volume of 896°, but whether steam at 283° with a relative volume of 490°, if allowed to expand to a volume of 896° will have a temperature of 244°, with the corresponding [illegible] an unsolved problem.

DEATH OF PROFESSOR SILLIMAN.—Professor Benjamin Silliman died at his residence in New Haven, Connecticut, on Thursday morning, 24th November, aged eighty-four. He has been professor of chemistry in Yale College since 1824. The *American Journal of Science and Arts* (better known as *Silliman's Journal*) was founded by him in 1818.

NEW ALLOY FOR IRON.—At the American Institute Professor Henry read a paper on a new alloy of copper, zinc, and tin, to be mixed with iron, recently patented by Mr. Arnold. It was stated that 5 to 10 per cent. of the mixture added to cast-iron increased the tensile strength of the iron several thousand pounds to the square inch, as proved by tests at the West Point Foundry.

PROFESSOR D. E. HUGHES.—It seems that many inventions are the result of accident. When Hughes invented the printing telegraph improvement, he was endeavouring to contrive a machine for copying extempore music, so that his melodious improvisations might not be lost. Boarding in the same house with him were the well known musical composer, Louis Hart, and the very intelligent telegraph operator, Norbonne M. Booth; one gave him the use of a piano, the other supplied him with electro-magnetic instruments; a printing telegraph instrument was the consequence. Hughes is now living in Europe, enjoying the well-merited fortune which his genius has earned. At the time of his residence in Kentucky, he was twenty-two years of age, a beardless boy in face and stature, and apparently lacking in mental power. His features were careworn; when spoken to he had a constant grin or giggle, not calculated to impress his interlocutor favourably. His ear for music was so acute that he could tell to a semi-tone the note of anything sounded, from a dry stick to a shovel.—*The Telegrapher.*

THE ELECTRIC CURRENTS OF THE EARTH.—M. Matteucci, in a second memoir, has reported to the Academy at Paris the continuation of his researches on the relations which may exist between these currents and atmospheric electricity, and also his verification of the results already obtained by the study of the currents upon lines whose extremities were plunged into the earth at different levels. Our limited space prevents us from giving details of the mode of experimenting, &c. He reports the results which he obtained by operating on telegraphic lines of great length. He worked most successfully on three lines in the valley of Aosta at different levels. The electric currents obtained in spite of much greater resistance, gave currents and fixed deviations much stronger than those observed in previous experiments on a hill near Turin. The experiments were made at very different hours, but the fixed deviation indicated in all cases an ascendant current in the metallic wire, as in the preceding experiments. In a great many cases the needle remained at the same angle of deviation during the whole duration of an experiment, sometimes an hour; but M. Matteucci states that he has also remarked, when there has been no change in the aspect of the sky, a nearly periodical movement in the needle. He says that, in spite of all the inherent difficulties connected with these studies, which should impose on the philosopher very great reserve in his conclusions, he thinks that he may consider the following result as established upon a great number of conformable facts obtained under very different circumstances:—"When a metallic wire is stretched over the earth, and isolated from it, with its extremities communicating with the earth at two points, at different heights, an electric current circulates constantly in the wire, the cause of which can neither be attributed to the chemical actions of the electrodes nor to those of the terrestial layers into which they are plunged. This current is constantly directed to the metallic wire of the highest point, and its intensity is greater in the longest lines, whose difference of level at the extremities is great. The intensity of the current does not sensibly vary with the depth of the cavities into which the electrodes are plunged, and is the same in the wire suspended at several metres from the earth as in the wire in contact with the earth."

THE SCIENCE OF CHEMISTRY.—This science is not only of advantage to agriculture, physics, mineralogy, and medicine, but its phenomena are interesting to all men. The applications of this science are so numerous that there are few circumstances of life in which the chemist does not enjoy the pleasure of seeing its principles exemplified. Most of those facts which habit has led us to view with indifference are interesting phenomena in the eyes of the chemist. Everything instructs and amuses him; nothing is indifferent to him, because nothing is foreign to his pursuits; and nature, no less beautiful in her most minute details than sublime in the disposition of her general laws, appears to display the whole of her magnificence only to the eyes of the chemical philosopher. All material bodies are the subjects of chemical research. The solid and fluid matter composing the terraqueous globe which we inhabit, also air, light, and heat, are subjects proper for the examination of the chemist. The arts of dyeing, bleaching, tanning, glass-making, printing, working metals, &c., are purely chemical. The vegetation of plants and some of the most important functions of animals have been explained upon the principles of chemistry. By means of this science agriculture and gardening have been greatly improved in Britain and other countries. Chemistry directs the labours of the husbandman and the rural economist. In the dairy, milk cannot be kept sweet and fresh, and butter and cheese cannot be made, without skill founded on chemical principles. Cookery and the art of curing and preserving beef, bacon, hams, and all animal and vegitable substances, are entirely chemical. The art of brewing, distilling, and making all sorts of fermented liquors depends upon the principles of chemistry. In medicine and pharmacy great benefits have been derived from the discoveries of chemical philosophers. The chemist resolves bodies into their elementary principles, and he examines their nature and properties when in a detached or simple state. He thus discovers their mutual relation to one another, and can recombine them in proportions different from those in which they were originally united. Hence new and useful compounds may be formed which nature does not produce. But chemistry is not only valuable as an art which supplies many of the wants, comforts, and luxuries of life. Its objects are sublime and beautiful in other senses; for it is intimately connected with most of the phenomena of nature, as clouds, rain, snow, dew, wind, earthquakes, &c.—*American Paper.*

MICROSCOPIC NEWSPAPERS.—The question, what will newspapers come to, with the price of white paper continually advancing, is one which publishers would like to be able to answer satisfactorily to themselves and to the public. Paper is now more than three times the price that it was before the war. Some newspapers put up their prices correspondingly, others diminish their size to meet the increased expenses. The latter resource as a remedy is, vulgarly speaking, "played out," for the newspaper has not a margin to act upon it in the descending scale anything equal to the ascending scale of prices with the paper-maker. A reading public want something larger than a Treasury note for a newspaper, though Treasury notes are considered valuable reading if people only have enough of them and of the right denomination. Intrinsically, paper is becoming, like gold, an article of value; and nobody who has to buy it ever speaks of it contemptuously as "rags," probably because a great deal of it is nothing but straw. The resources of chemical and mechanical art fail to supply a remedy to the publishers' distress; the only one we can think of in this emergency is suggested by a combination of the science of optics and the art of photography. Mr. Langenheim, the ingenious and enterprising photographer, has succeeded in impressing the whole of the Lord's Prayer upon a photographic print scarcely larger than the head of a pin, which, under a microscope, can be so brought out that any person who has eyes can read it. Now we suggest that as paper is so valuable, the "forms," or types as arranged for newspapers, ought to be photographed in the same way, and each purchaser should provide himself with a good magnifying glass, so as to bring the reading out to the right size. This would be such a saving in the consumption of paper that the manufacturers would soon be willing to compromise with the publishers, and let them have paper at a reasonable price. There would be an advantage to the reader as well as to the publisher in this arrangement. By using greater magnifying power, the reader could make the type suit his eyes, and increase it to any reasonable size, removing at once all cause of complaint that the types are too small. Those who are fond of big stories and swelling head lines could magnify them to any size they please, and get the worth of their money in astonishment if not in information. Politicians could give greater emphasis to their big, round expletives when viewed through such a medium: the only drawback would be that their libels upon each other would look so large that they would be ashamed to see them next day staring them in the face. A candidate for office, jealous of the reputation of an opponent, could so diminish his praises, by a skillful application of the glass, that he could see no merit in the individual at all. If the paper manufacturers could be compelled at once to look at their prices through a continually diminishing medium, there might possibly be no necessity for the improvement we have suggested.—*Philadelphia Ledger.*

THE INTRODUCTION OF GUTTA-PERCHA.—The success of the submarine telegraph, which was first demonstrated in 1851, when the deep-sea cable was laid down in the English Channel between Dover and Calais, entirely depended upon a single point. No submarine cable could be used for telegraphic purposes until its insulation was rendered perfect. Only one material was known to possess this insulating property, as being at the same time indestructible by water, and a bad conductor of electricity. This substance was gutta-percha, now so well known to every one in an infinite variety of forms, but which, only twenty years ago, had scarcely been heard of. It was in 1842 that Dr. Montgomery, an assistant surgeon to the Residency at Singapore, sauntered out one day in the neighbourhood of that city. His attention was attracted by a native woodcutter at his work, and the doctor was struck by the appearance of the hatchet which the man was using. It seemed to be both strong and flexible, and did not resemble any substance which the doctor had ever seen employed for that purpose. On questioning the man, he learnt no more than that the mysterious material could be made into any form by dipping it into boiling water till it was heated through, when it became plastic as clay, regaining, however, when cold, its original hardness and rigidity. Struck by these facts, Dr. Montgomery inquired further, and soon discovered what he had suspected, that gutta-percha, like india-rubber, was a gummy substance which oozed out from between the bark and the wood of certain forest trees, and that it could be had in great abundance. The great utility of such a substance in the arts at once presented itself to his mind. He obtained specimens in various stages of preparation, and sent them to the Society of Arts in London. The society subsequently conferred a gold medal upon Dr. Montgomery. But the substance had already been seen in Europe. Even as early as the time of Charles I., the well-known botanist, Tradescart, had brought hither a specimen of this curious product, under the name of mazer-wood, and it had subsequently been often brought to Europe under the general name of india-rubber, in the form of elastic whips, sticks, &c., but had never attracted much attention. It was in the year 1844 that two hundredweight of this new article of commerce was shipped as an experiment from Singapore. The exportation rapidly increased. In the first four years and a half of the

trade 21,598 piculs of gutta-percha, each picul weighing about 133 lbs., were shipped at Singapore, the whole of which were sent to England, with the exception of 15 piculs to the Mauritius, 470 to the continent of Europe, and 922 to the United States. But the rapid growth of the new trade conveys only a faint idea of the commotion it created among the native inhabitants of the Indian Archipelago The jungles of the Johore were the scenes of the earliest gatherings, and they were soon ransacked in every direction by parties of Malays and Chinese, while the indigenous population gave themselves up to the search with a unanimity and zeal only to be equalled by that which made railway jobbers of every man, woman, and child in England about the same time. The knowledge of the article stirring the avidity of gatherers, gradually spread from Singapore northward as far as Penang; eastward to Borneo, where it was found at Brune, Sarawak, and Pontianak on the west coast; at Keti and Passer on the east.

The Aurora Borealis and the Telegraph.—The effect of the aurora borealis on electric telegraph lines is curious. In September, 1851, there was a remarkable aurora which took complete possession of all the telegraph lines in New England, in the United States, and prevented any business being transacted during its continuance. In February, 1852, another instance occurred. Towards evening a heavy blue line appeared upon the paper used by the operators, which gradually increased in size for the space of half a minute, when a flame of fire succeeded to the blue line of sufficient intensity to burn through a dozen thicknesses of the moistened sheets. The current then subsided as gradually as it had come on, until it entirely ceased, and then succeeded by a negative current (which bleached instead of colouring the paper). This gradually increased until it also, in turn, produced its flame of fire, and burned through many thicknesses of the prepared paper. The effect of the aurora borealis, or magnetic storm, appears to be totally unlike that of common or free electricity, with which the atmosphere is charged during a thunderstorm. The electricity evolved during a thunderstorm, as soon as it reaches a conductor, explodes with a spark, and becomes at once dissipated. The other, on the contrary, is of very low tension, remains upon the wires sometimes half a minute, produces magnetism, decomposes chemicals, deflects the needle, and is capable of being used for telegraphic purposes, although, of course, imperfectly. The aurora borealis has in fact been used for transmitting and receiving telegraphic despatches. This almost incredible feat was accomplished in the forenoon of the 2nd September, 1859, between the hours of half-past eight and eleven o'clock, on the wires of the American Telegraph Company between Boston and Portland, and upon other lines in various parts of the country, as described by Mr. G. B. Prescott, the able superintendent of the American telegraph lines. The auroral influence was observed one day upon all the lines running out of the office in Boston, at the hour of commencing business (eight o'clock, A.M.). and it continued so strong up to half-past eight as to prevent any business being done, the ordinary current upon the wires being at times neutralized by the magnetism of the aurora, and at other times so greatly augmented as to render operations impracticable. At this juncture it was suggested that the batteries should be cut off, and the wires simply connected with the earth. The current from the aurora coming in waves of greater or less intensity, there were times, both while the wave was approaching and while it was receding, when the instruments were enabled to work; but the time varying according to the rapidity of the vibrations, whatever business was done upon the wires during these displays had to be accomplished in brief intervals of from a quarter to half a minute duration During one of these intervals, the Boston operator said to the one at Portland, "Please cut off your battery, and let us see if we cannot work with the auroral current alone." The Portland operator replied, "I will do so. Will you do the same?" "I have already done so," was the answer. "We are working with the aid of the aurora alone. How do you receive my writing?" "Very well indeed," responded the operator at Portland; "much better than when the batteries were on; the current is steadier and more reliable. Suppose we continne to work so until the aurora subsides?" "Agreed," replied the Boston operator. "Are you ready for business?" "Yes; go on," was the answer. The Boston operator then commenced sending private despatches. The line was worked in this manner more than two hours, when, the aurora having subsided, the batteries were resumed.

PATENTS.

APPLICATIONS FOR LETTERS PATENT.

3057. C. Oliver, improvements in apparatus for sounding bells on lighthouses, alarm bells on public and private buildings, and for bells in chapels and places of worship.

3074. T. Wood, improvements in means or apparatus for communicating and signalling on railway trains, and for securing the doors of the carriages.

NOTICES TO PROCEED.

1924. M. Woodiefield, improvements in apparatus for communicating between passengers and guards and between guards and engine-drivers on railway trains.

1979. A. Turner, improvements in apparatus for enabling the passengers in a railway train to communicate with the engine-driver and guard, and the guard and driver with each other, while the train is in motion.

2023. J. Dilkes and E. Turner, improvements in apparatus for facilitating communication between passengers, guards, and drivers, travelling by railway trains.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2710. R. C. Robinson, improvements in semaphoric signals applicable to railway carriages.

2868. G. Score and R. W. Sievier, improvements in the means of communication for railway travellers with the guard.

2926. J. S. Gisborne, improvements in mechanical apparatus by which motion can be communicated or transmitted from one place to another, and between different parts of a ship or other structure to exhibit orders, messages, or signals.

2935. R. Wheble, improvements in the means and apparatus for communicating between passengers, guards, and drivers of railway trains.

PATENT SEALED.

1538. W. J. Pughsley, improvements in obtaining sulphuric acid from the refuse of "pickle," used in tin-plate works, and also from sulphate of iron or "green copperas."

PATENTS WHICH HAVE BECOME VOID.

2961. W. Clark, improvements in the construction of parts of electric telegraph bell apparatus, and in apparatus used in making the same.—A communication.

2987. E. C. Shepard, improvements in magneto-electric machines.

3002. P. Spence, improvements in the treatment of ores for the manufacture sulphuric acid, and in apparatus connected therewith, which apparatus is also applicable to the treatment of ores for separating metals therefrom.

PATENT ON WHICH THE STAMP DUTY OF FIFTY POUNDS HAS BEEN PAID, AND DATE OF ITS PRODUCTION FOR CERTIFICATE.

3078. C. F. Varley, improvements in electric telegraphs.—Dec. 9th, 1861.

WHAT IS ELECTRICITY?

Is it not a strange question to ask at this day? Surely we know what it is. It is familiar to us all. In how many ways do we not use it? As messenger, as coast light, as motive power; to plate our spoons, to ring for our servants, to catch our fish, and also catch our thieves; to light our gas, to tell the time, to watch our idle servants. We use it in metallurgy; in the fine arts to cast our medals, vases, and statuary. We use it in surgery and therapeutics. We use it to spring our mines, to fire our torpedoes, and mark our targets, and for many other purposes—so many that no ordinary memory can contain them. Still, what is electricity?

So wonderful is this thing to me, that I have an unquenchable desire to know it face to face. For this purpose I read our authors, who treat learnedly upon it. I read reports of committees and commissioners, who sit and consult, and take evidence upon it. I converse with men who are wondrous learned in the matter, and try to get their notion of what this thing is. Then I try to collect together the sum and substance of all that I have read and talked about it, and try to put all these multifarious notions, or opinions, or guesses, or I know not what, except that they are certainly contradictions one of the other, into some form to be understood by me if possible; but hitherto it has not been possible. First, I am told that there are five or six kinds of electricity, if not more: that there is static electricity, voltaic electricity, magneto electricity, thermo electricity, photo electricity, and I know not what other kind. Then I am told it is all the same—there is only one kind. Still, that does not satisfy me, for I am told by the report of a committee that static electricity is electricity at rest; yet even then it can produce an effect, and what is more puzzling, this same effect is produced at a distance without a nexus, because I am told that the intermediate air is a non-conductor. But even if it were not, that would not help me, for the electricity is said to be at rest; consequently, cannot be conceived to pass across that interspace of air, for if it did, it would not be at rest; yet there is an effect produced, and it is said to be according to the square of the distance. Well, now, I wish that learned committee had made that report square somewhat with our notions of what can and cannot be. Here is a marvel of impossibilities. Electricity a somewhat, which is at rest, yet effects something at a distance, and without a nexus! The report of the sub-committee for finding out a standard of electric resistance says so. From that can you make out what electricity is? Can anything act when it is at rest? Moreover, can it act in a place where it is not, neither itself nor by a nexus? What is to become of the pupil when the teacher's head goes wrong like that?

There is dynamic electricity also as well as static. This dynamic electricity is said to be made up of two fluids, or else of two forces—many authors say fluids; this last report affirms forces, still speaks of them as fluids; but I think all agree that there are two, whether force or fluid. And the one is called positive or plus, or the overmuch, and the other is called negative or minus, or the overlittle, and that the two, when added together, make zero, or nothing. A notable conclusion!

"Out of nothing nothing comes." Now, what is electricity? Is it an idle question after that? But this is not half the difficulty. To return to what is called static electricity, we are told that there are two kinds of it also. The one kind is a something, and the other is a nothing and less, for the two added together make nothing; the two are called positive and negative fluids or forces; they are also called vitreous and resinous electricity—that is to say, what is called positive electricity is excited on glass by it being rubbed, and negative electricity is excited on sealing-wax, and that these two kinds can be isolated, and any portion of either carried away upon a suitable conductor; but if equal portions of the two be added together, then there is no electricity or a state of neutrality. Furthermore, it is stated that the electricity, which is something, can never be excited without that electricity which is less than nothing making its appearance also, and that this extraordinary occurrence takes place through the decomposition of a neutral electricity whose constituents are this something—vitreous, positive fluid, or force; and this less than nothing—resinous, or sealing-waxous, or negative fluid, or force; and that this neutral, neitheral electricity must be zero or nothing, for the two electric fluids or forces when added together make zero or nothing.

Who knows what static electricity is? It is a fluid; it is a force; it is something; it is nothing; it is less than nothing; it is neutral; it is zero; it acts at a distance, and at the same time is at rest; it repels; it attracts; it thrusts without touching; it pulls without any hold. What is there on earth so wonderful as this? or in the heavens above? or in the waters under the earth?

Our learned authors wrote all this, and their disciples repeat it after them, and look so wise, as if they were the mouthpiece of an oracle; and a poor would-be learner like me (if I could only find a teacher) is sneered at as an ignoramus. No, I cannot understand it, if, as it is stated, that the current in a battery flows from zinc to copper, and in the external circuit from copper to zinc; because they say, "Zinc to cable, charge one minute, discharge one minute; copper to cable, charge one minute, discharge one minute, leakage, &c." How can zinc to cable charge it, I wonder, when no current flows out at the zinc, as it is said? Oh, yes; I know that it is said that in this case you charge it with a negative current; and commissions get evidence in such form of words, and sub-committees write reports in such form, and they do not expect to be laughed at. Not they, for they think they are talking most rationally and learnedly. Well, perhaps we are all a little bit touched together, and each thinks the other demented, as is the habit with mad people.

Nevertheless, I have always conceived, and, I think, I have heard some one say so too, that the laws that govern this universe are simple. Yes, and if they be understood, they can be put down in a rational form of words. But where do we find a rational treatise on electricity, a rational chapter—I had almost said, a rational sentence? There may be this last; I do not say there is not. We will say nothing of minutes of evidence, nor reports of sub-committees. These are full of mathematical analytics,—that shows learning; but of the ordinary every-day common sense there is not much. We have a committee, who have been at work these four or five years finding us an "absolute" measure of electrical resistance in "absolute units." At least, they say they either have found these "absolute units," or are going to do it. Absolute! What is an absolute unit, I wonder? I thought all measures were relative; and I think so still. Is "the absolute" going to be

ground out of that machine at King's College, I wonder. A marvellous feat! A fallible machine that, and liable to many errors; but then the theory of that machine is down in algebraic symbols, and it is worked out. All its errors are demonstrated and allowed for. We shall see. I wonder if they expect more or fewer errors in the conclusion than they put in the premises. You can prove what you will, only take care how you state your premises.

I do not find fault with our electricians for not telling us what electricity is. I do not expect that from them yet. But I, with all other students of electricity, I think, have fair cause for complaint in that they write about electricity in contradictions language, which, if it means anything at all, it is impossibilities, absurdities, nonsense. It is sheer impertinence to get themselves called professors and teachers; they clearly do not know any more than we.

INDOCTUS.

ELECTRO MAGNETS.

CONTRIBUTED BY PROFESSOR D. E. HUGHES.

Being desirous of constructing the best possible electro magnet for telegraphic purposes, and several apparently contradictory results having been obtained, I was induced to investigate very closely the *known* and *unknown* laws regarding the subject. From the commencement of these experiments, the necessity was felt of using an electro chronograph, which would give the correct measure of force obtained on the electro magnet with the correct division of time necessary for the current to produce its maximum effect upon the iron cores of the electro magnet.

Upon reflection, I determined upon using my printing telegraph instrument, which, with some slight modifications for this purpose, most admirably suited the purpose desired. By the aid of this instrument, the time necessary for an electro magnet to pass from its minimum to its maximum of force could be accurately obtained, showing also the amount of force obtained during any fraction of this time. The curves of force so obtained show that for all practical purposes the maximum of force would be obtained by a contact of 1-16th of a second, and that this increase of force, if divided in four divisions of time, would be as 8, 4, 2, 1. Divisions of time equalling 1-1000th of a second of time could be accurately obtained, and in the same time a record made of variations of electro magnetic force from one gramme up to 300 grammes. These results are perfectly constant, no matter what form or size of electro magnet or armature, the only difference being in the increase of the curve.

With ten or three elements, with or without external resistance, the time of passing from its minimum to its maximum was invariably the same. For all practical purposes the maximum of effect would be obtained by a length of contact which would equal 1-28th part of a second, and if we allow the same time for discharging the electro magnet, fourteen currents per second can be sent through an electro magnet for telegraphic purposes, producing the maximum of effect. The retardation caused by the induction of a given line should also be deducted from this speed, allowing probably upon a well constructed air line of a speed with maximum effect of ten contacts per second.

The first step in this investigation was to find what amount of resistance of wire on the electro magnet would produce the maximum effect. For this purpose 500 kilometres of line resistance was chosen, having an average loss of two-thirds of the actual current to earth. This loss could be made greater or smaller, in order to represent the actual working of an air line. After numerous experiments it was found that 120 kilometres' resistance, or sixty on each coil, would give the best average results, taking into consideration all the changes that an actual telegraph line has to undergo during different periods of time. The numerous curves obtained from these experiments would be too long to publish here, but we may state that the highest average curves obtained through different losses were always obtained with the coils having sixty kilometres resistance each.

The next step in this inquiry was to find the proper form and size of the iron cores in the coils of the electro magnet, and from the commencement two very important qualities manifested themselves in different bars of iron submitted to trial. It was found that different bars of iron conducted the magnetism produced in a greater or lesser manner, and that the total magnetic result would be directly as the conducting power of the bar of iron. Thus suppose we take bars of soft iron and steel equal in length and diameter, we shall find by placing a natural magnet at one end of the bar, and then observing how much magnetism is conducted to the free end, that the iron bar will support eight times more weight than the steel placed in the same circumstances. Thus we can easily determine the conducting powers of soft iron to be eight times that of tempered steel, and when placed in the electrical coils, the steel bar required eight times the amount of current to produce the same amount of magnetic force at its free poles, thus showing how important it is to choose the softest iron. The annealing of an ordinary iron bar produced eighteen per cent. difference in favour of the annealed bar. All parts, such as the armature, &c., should be perfectly annealed, as the smallest piece of hard iron reduces the results sensibly. Care should also be taken that the fibres of the iron are longitudinally, reducing the results sensibly if they are transversely. For this reason, a drawn iron tube or wire have been generally found superior for the cores; the greatest difference observed was from ten to fifteen per cent.

Another very important quality of iron, and which we believe has not yet been noticed in its connection with electro magnetism, is the power of absorption of the magnetism in iron. This absorption of the magnetism, or, in other words, that in which the magnetism becomes latent is very remarkable in different species of iron, and with the same iron the amount absorbed is directly as the mass. If we lay upon a bar magnet a piece of iron we shall find that the magnet will support less weight than before, and the difference will be exactly as the amount absorbed by the piece of iron on the magnet. If we now place a piece of hard steel of the same size we shall find that the difference in their absorbing powers are not more than one-sixth, and that the iron has absorbed but one-sixth more than the tempered steel, whilst its conducting powers are eight times. Coils were constructed, having for its core a thin tube of iron one centimetre in diameter, six centimetres in length, and one-quarter millimetre in thickness. They were so arranged that tubes of different thickness could be placed inside. The curves of force obtained with different thicknesses of iron core proved completely that the maximum of effect was arrived at when the core possessed a thickness of one and a-half millimetre.

After this point had been reached, the iron having already conducted all the magnetism generated to the poles, the adding of iron produced a diminished effect caused by the absorption of the maximum magnetism already generated, and thus a certain quantity which was conveyed to the poles became absorbed in the unnecessary iron which was added. This experiment was repeated in a variety of ways, with cores of fine iron wire, with solid bars, and with large and small tubes, proving that where the maximum of conducting power with a given force had been obtained by a certain amount of iron, any additional amount would be prejudicial to the result, a certain portion of the magnetism induced then becoming absorbed in the unnecessary iron. As regards the length of coils and bars, the maximum of effect was obtained in every case with six times in length the diameter of the bar.

Supposing a bar of iron several metres in length, and one centimetre in diameter, had separate coils of the same resistance during its whole length with the same power on each coil, no greater effect would arrive at the poles than one coil six centimetres long, simply from the resistance to conduction of the magnetism generated. Thus, it is of the utmost importance before choosing any iron for the cores of an electro magnet to test it for conduction, taking hard tempered cast steel as a standard. With this standard bars of good iron, same diameter, should at eight times the length of tempered steel support the same weight. Tubes of iron were found the best adapted to a telegraphic electro magnet. Whilst having a sufficiently large diameter near the electrical coils, the amount of iron could be regulated so as to have its maximum of conduction with its minimum of absorption.

The results of these experiments show that the amount, as well as the quality, of iron, in a given electro magnet, to be used with a certain resistance, should be carefully studied; and for an electro magnet giving the highest average results, through 300 to 800 kilometres resistance, it was found that the total weight of iron, in cores connecting bar and armature, should be 80 grammes. Experiments were then made to find the best form of armature which would utilize the maximum of effect produced at the poles of the electro magnet. The same phenomena of conduction and absorption was observed in the different armatures. If the armature was too thin, the resistance to conduction was too great. If too large, the magnetism induced became latent, and a proportion was consequently lost to all practical effect.

It has long been known that the true poles of a magnet are situated at a short distance from the extremity, but no attempt has yet been made of putting this knowledge to practical use in the construction and working of electro magnets.

Projections or pole pieces were now added to the electro-magnet, in order to obtain a coincidence of the true poles of the armature with those of the projections, and the result of these experiments were most successful. The forces increasing rapidly as the true poles approached each other, and diminishing when this coincidence was passed. The armature thus shortened, became exceedingly sensitive and rapid in its action, working with a constant effect, and through a much larger variation of current than possible with the ordinary arrangements of armatures. The sensitiveness to feeble currents of the electro magnet thus arranged was very remarkable, one cell being amply sufficient to work the printing telegraph instrument at its ordinary speed of 120 revolutions of the type-wheel, sending five letters per revolution, or 600 letters a minute through a resistance of 1,000 kilometres, with a loss to earth of two-thirds of total current.

With simple resistance, a small piece of zinc and copper placed upon the tongue would work the magnet perfect and regular at 600 contacts per minute, through 1,000 kilometres resistance. On a resistance of 300 kilometres, a piece of gold coin and silver in water would produce sufficient current to produce the same effects. Experiments show that upon a given resistance and battery, and with so great a loss to earth, that the ordinary arrangement of armature, as in the Morse instrument, or a very sensitive galvanometer, could not indicate the slightest passage of current; by simply changing armatures, the instrument would most perfectly, showing strong indications of a current of sufficient strength to be of practical utility, even when the battery power was again reduced one half. Thus, by care in constructing the electro magnets, and adjusting the true poles of the armatures, a telegraphic line could be easily worked, when the current by loss on line had become far too feeble to make the arrangements heretofore used.

The practical results here mentioned were obtained in the application of these principles to my printing telegraph, rendering it thus very sensible to feeble currents, and at the same time allowing the facility of working without adjustment through a range of from 1 to 100 elements. The Morse relay magnet, constructed upon these laws, would, in my opinion, be more sensitive than before; but even then, the high results mentioned here could not be obtained, simply from the armature being acted upon at a certain distance, using only the minimum of force, whilst, in my printing instrument, the armature resting against the poles in a state of rest, the maximum of force is thus always obtained.

The result of these experiments are not theoretical deductions obtained from the laws shown in the foregoing experiments, but these laws are already practically applied in my printing telegraph instrument, as now working upon the most important and longest lines of the telegraphic administration in France.

"UNCLE SAM" IN REPLY TO "CHEROKEE."

I HAVE obtained Noad's 4th edition—which, I am told, is the latest—in order to compare "Cherokee's" quotations (*Telegraphic Journal*, 1st October and 3rd December) with the original.

"Cherokee" says (quoting Noad, I presume), "So that you see Mr. Wheatstone calls f the *electro-motive* force of a battery." But he says no such thing. Allow me to quote what Noad really does say (394). "*Let* F" (he does not use "f" at all) "*denote the actual force of the current*, E *the electro-motive force*."

Again, quoting the formula

$$f = \frac{nE}{\frac{nRD}{S}}$$

he says, "Mr. Wheatstone tells us, as above quoted, that no matter how S varies, the value of f does not vary." Noad and Wheatstone do *not* state this. Wheatstone's first law, "The electro-motive force is in no degree dependent on the dimensions of any of their parts," states that E, the dividend, not F, the quotient, is unaffected by an alteration in the divisor. "Cherokee" makes the verbal law differ from the formula by quoting erroneously and confounding the values of f and E.

I cannot find that Noad mentions the next question, "as to whether a battery will always do more work when the external and internal resistances are equal or not." I cannot, therefore, dispose of this case as summarily as I have done the first by showing what Noad really does say.

"Cherokee" certainly makes the "law" appear absurd, but I have never seen it stated in such a manner as to permit the construction he puts upon it. It is very easy to make any law appear ridiculous, if one is not careful to state it correctly.

Next, I allow at once that Noad states that "a resistance which might weaken to a considerable extent $\frac{E}{R}$ might not sensibly diminish $\frac{nE}{nR}$," and I accept "Cherokee's" criticism and way of stating the law.

Lastly, as to my "grave fault" in changing the value of R to "suit" my "emergencies," I pointed out (5th November) that the change had been made, and asked, "Who is accountable for the confusion?" I now find that Noad is in fault in this particular case.

Those who wish to see the laws of the current clearly stated should read Gavarret's second volume.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO ELECTRICITY AND MAGNETISM, THEIR GENERATION AND APPLICATION.

XX.

A.D. 1843, November 18.—No. 9946.—Wall, Arthur.—"Certain improvements in the manufacture of iron." This invention consists in the use and application of certain "substances, and of the agency of electricity in the manufacture of iron." Either operation may be applied "independently of the other." In the second operation, the metal is subjected, "whilst in a fluid state, and also whilst in the act of congealing or solidification, to a current of electricity," which is caused to traverse as completely as possible throughout the entire "metallic mass." When the metal runs into a mould it may be made to complete the electric circuit, or it may run around or over a wire included in the circuit. Any kind of electricity may be used, but that from a Grove's or Smee's battery is preferred. The current may be transmitted during solidification, and then stopped; or in casting ordnance it may be continued for some time after the metal has entirely solidified. "In applying electricity to iron in a smelting furnace or cupola," one battery pole is inserted at the tap hole, and the other "into the upper and posterior part of the hearth, or in at one of the tuyre holes or apertures," both poles being in contact with the iron. "In applying electricity to the iron in the pudding or balling furnace," a rod connected with one pole is inserted into one part of the fused metal, and a rod connected with the other pole has an insulated handle attached to it, so as to enable it to be moved about; "thus making the electrical current pass through the metal in every possible direction."

A.D. 1843, December 8.—No. 9982.—Schottlaender, Julius.—1st. "Improvements in the deposition of metals by electric agency upon various felted and other fabrics, such as cloth, linen, leather, glass, earthenware, and the like substances, not being themselves conductors of electricity." To cover "linen or other cloth with a surface of metallic copper," it is cemented by the edges to the plumbagoed surface of a copper plate or matrix, and immersed in a solution of sulphate of copper, in connection with a galvanic battery and dissolving plate in the usual manner. The process may be continued until the copper has penetrated to the exterior of the fabric. The cupreous surface given to the material is plain or ornamented, according to the pattern of the matrix. Three apparatus for metallizing a length of fabric are described and shown; one, consisting of a roller immersed in the trough, round which roller the fabric is made to pass slowly. Another, in which sulphate of copper solution is made to drop upon a felted copper roller forming the positive metal, the fabric passing between this and another roller which forms the matrix. A third, in which the fabric is affixed to copper matrices, placed round the sides of a single cell trough containing zinc and salt, and water, in porous cells, and solution of sulphate of copper. Details of working, and relating to other materials to be metallized, are given. 2nd. Improved batteries for generating electricity. The "concentric battery;" cylinders of copper and zinc separated by porous cells, and placed alternately. The "mercurial battery;" "alternate series of copper and mercury, separated by porous diaphragms, and immersed in a solution of sulphate of copper." The "magnetic battery;" "two circular arrangements of horseshoe or other magnets, placed one within the other." The outer circle of

This method is applicable even to those cases in which the electro-motive force to be measured is incapable of maintaining a current. The laws of chemical electrolysis and electro-magnetic induction afford two other indirect methods of estimating electro-motive force in special cases.

29. *Measurement of Electric Resistance.*—We have already stated that the resistance of a conductor is that property in virtue of which it limits the amount of work performed by a given electro-motive force in a given time, and we have shown that it may be measured by the ratio $\frac{E}{C}$ of the electro-motive force between two ends of a conductor to the current maintained by it. The unit resistance is, therefore, that in which the unit electro-motive force produces the unit current, and therefore performs the unit of work in the unit of time. If in any circuit we can measure the current and electro-motive force, or even the ratio of these magnitudes, we should, *ipso facto*, have measured the resistance of the circuit.

30. *Electric Resistance in Electro-magnetic Units is measured by an Absolute Velocity.*—The dimensions of R are found, by comparing those of E and C, to be $\frac{L}{T}$, or those of a simple velocity. This velocity, as was pointed out by Weber, is an absolute velocity in nature, quite independent of the magnitude of the fundamental units in which it is expressed. The following illustration, due to Professor Thomson, will show how a velocity may express a resistance, and also how that expression may be independent of the magnitude of the units of time and space.

Let a wire of any material be bent into an arc of $57\frac{1}{4}°$ with any radius, k. Let this arc be placed in the magnetic meridian of any magnetic field, with a magnet of any strength freely suspended in the centre of the arc. Let two vertical wires or rails, separated by a distance equal to k, be attached to the ends of the arc; and let a cross piece slide along these rails, inducing a current in the arc. Then it may be shown that the speed required to produce a deflection of 45° on the magnet will measure the resistance of the circuit, which is assumed to be constant. This speed will be the same whatever be the value of k, or the intensity of the magnetic field, or the moment of the magnet. In this form the experiment could not be easily carried out; but if a length, l, of wire be taken and rolled into a circular coil at the radius, k, and the distance between the vertical rails be taken equal to $\frac{k^2}{l}$, then, if the resistance of the circuit be the same as in the previous case, the deflection of 45° will be produced by the same velocity in the cross piece, measuring that resistance; or generally, if the distance between the rails be $p\frac{k^2}{l}$, then p times the velocity required to produce the unit deflection (45°) will measure the resistance. The truth of this proposition can easily be established when the laws of magneto-electric induction have been understood.

IMPROVED METHOD OF COMMUNICATION FOR RAILWAY PASSENGERS.

A new and valuable mode of communication between passengers and the guards of a railway train has been designed by Mr. W. H. Preece, C.E., and has been experimentally tried on the London and South-Western line during the past week with great success. In the construction of the apparatus, Mr. Preece has had recourse to both mechanical and electrical appliances, and the result is an easy, cheap, and perfect system of communication, which every traveller would gladly see accepted by the various railway companies. On Friday, December 16th, this unique contrivance was exhibited for the first time at the railway terminus, Southampton. The apparatus was fixed to a first-class carriage, and a connection having been effected with the guard's van by means of electric wires, the efficiency and simplicity of the communication were demonstrated in a most complete and successful manner. The apparatus will be submitted to the authorities in London this day (Saturday), and we have no doubt that its thorough practicability will secure for it their unqualified approval. This is a question which has for some time occupied the most earnest attention of the railway companies, and a committee has been formed by the railway clearing house, consisting of some of the principal railway managers, to report upon the best plan. Upwards of 200 plans have been submitted, none being found equal to the requirements demanded of such a contrivance. In establishing an effective system of communication between passenger and guard, four points are desiderated as necessary to ensure a practical and useful result:—1. The means of creating an alarm must be easily accessible to every passenger. 2. It must have a means of indicating the particular carriage that requires attention which cannot be replaced by the passengers. 3. It must sound a gong or ring an alarum, which must be unmistakeably heard by the guard. 4. The guard must have the power of attracting the attention of the driver from any portion of the train. There are two plans which have met with considerable favour, and have been carefully tried, but with no decided success at present. These are Tattersall's, which has been fitted on one of the South-Western Railway carriages, and Woodiefield's has been tried upon the Great Western line. The former effects the required object by means of mechanical, and the latter by means of electric force. It is considered hopeless to attempt to carry out all the necessary requirements by the aid of mechanical apparatus alone, and it is felt that the only means at the disposal of engineers to enable them to do so at all effectively is the use of electric force, or of mechanical and electric appliances combined. There are many prejudices against the employment of electricity for such useful purposes as ringing an alarum, sounding bells, &c., but these prejudices only exist through ignorance of the real properties of the force. It is imagined that the use of batteries would be attended by great inconvenience and trouble, and would need an undue amount of attention; but batteries are now constructed which require no attention for twelve months. Electricity is a force which is destined to accomplish an immense amount of useful service in our various domestic and public wants, and the better it is understood the more it will be appreciated and used. The new communication which Mr. Preece has designed is carried out by a combination of mechanical and electrical appliances. Immediately above the seats, between the soft padding and the net rack, is fixed an ordinary bell-rope and tassel, which is easily accessible to every passenger in the compartment. Where the compartment is divided into several seats, each seat has a separate pull; but where no division exists, the bell-rope is placed in the centre of the compartment. The motion of this rope by its seizure or strain in the carriage is transferred by wires and pulleys to catches fixed at the two opposite corners of the carriage, which release two semaphore arms that fall and indicate unmistakeably to the guard the particular carriage that requires attention. These semaphore arms are excedingly distinct, and as they fall simultaneously on either side of the carriage in whichever direction the train is going they are instantly observable. They cannot be replaced by any one but the guard, and their fall completes the electric circuit, which sets in motion a bell in the guard's van, or in each van should there be more than one, and which will ring incessantly until the arm is restored to its original position. If, when the guard reaches the carriage which has raised the alarm, he finds it necessary to stop the train, he can, by means of his key, ring a bell on the engine, which will warn the driver that he must stop. Two wires are carried down the train underneath each carriage, the connection being maintained by very ingenious hook and eye couplings. Attempts have been made to adopt the regular couplings of the carriages, but their electrical action is not sufficiently reliable to depend upon their use. The couplings used are very trustworthy, and easily manipulated, and the whole details of the apparatus are as simple in their mode of working as they are cheap in their construction. Two compartments of a carriage have been fitted up on this principle, and the third has an electrical button alone, which rings a bell without exposing any indicator. This is done more to show the practicability of using electricity for such a purpose than to exhibit a complete communicating apparatus between passengers and guard. The semaphore arm is believed to be of itself a sufficient indicator for both night and day use, but it is an easy matter to make it display a red disc at night by means of a lamp. This system is believed to be the best yet introduced. It combines all the advantages of Tattersall's with the additions of Woodiefield's, and carries them out in a simple, mechanical manner, easily and cheaply applied to existing rolling stock. Its introduction would afford a security to railway passengers which is denied to them by the existing system, and the public demand for such protection has been so loud, that if railway companies do not take the matter up, the Legislature undoubtedly will.

THE ATLANTIC CABLE.

A circumstantial account of the commencement of shipping the Atlantic electric telegraph cable, published in an evening paper on the 10th inst., and copied by several of our contemporaries next day, is, though inaccurate in all the particulars, within a fortnight of probable truth as regards the main statement which it contains. The operation of transferring the cable from the factory at East Greenwich to the hulks Amethyst and Iris has not yet been begun; but, if all should go well, the preparations for this important step in the great enterprise may be concluded before New Year's Day. Meanwhile, it is necessary to correct the utterly erroneous report which has appeared on the subject, and which seems to be indebted for its figures to the back numbers of a scientific journal. Those figures in reality represent no more than the prospective calculations of gentlemen superintending the works—that is to say, they refer to possibilities, not to accomplished facts; and in hardly one instance will the actual result verify the account which gravely purports to be a description of what has already been done.

The works of the Telegraph Construction and Maintenance Company, formerly Messrs. Glass & Elliot's, are now the scene of as marvellously delicate a labour as ever yet taxed human intelligence and skill. The engineer and the electrician unite all their finest energies in the accomplishment of an end which must be universally pronounced the triumph of our century; and the combined process of fashioning this wondrous coil,

and testing its uninterrupted conducting powers throughout the entire length, is an affair so complex as to baffle the understanding of any but experts, while even they will be moved to admiration by a sight of the means adopted to ensure a perfect result. Powerful machinery, by which some fourteen miles of the "core," or gutta-percha-coated copper wire, are worked up into cable every day, is not the most important agency; for the tons of material, during manufacture, must undergo the trial of those exquisite instruments over which the man of science bends watchfully hour after hour, ready not only to detect a fault, but to apprise the engineers at what exact distance in the cable it has occurred. Moreover, the necessity of guarding against every slight inadvertence, every possible act of mischief, involves a constant inspection rarely exercised within the walls of a factory. The personal characters of all the workmen, and of the persons employed to cart the large reels of core from the Gutta-percha Works in the City-road to East Greenwich, are the object of rigorous inquiry; and in case of any defect in the cable being found, its exact point can actually and infallibly be identified with the name of the workman responsible for that part of the work.

We shall now endeavour to give, as succinctly as possible, and from data afforded us by inspection of the works as well as by the courtesy of the chiefs of departments, an account of what is doing at Morden Wharf and a factory in its neighbourhood. At this last-named establishment the covering for the core is fabricated from iron wire and Manilla yarn, which is afterwards steeped in a seething compound of tar and gutta-percha. If a section of the perfected cable be examined, it will be found to measure an inch and one-eighth in diameter, the seven conducting wires lying close together in the middle. They are surrounded by layers of gutta-percha, the rings of which may be faintly discerned, though they form a substantial and practically homogenous coating, about a sixth of an inch thick. So far, we have the core, which is supplied from the gutta-percha works in the City-road, before leaving which place it has undergone the same tests which are afterwards applied during the process of covering at East Greenwich. In the section, we shall further perceive that the core is surrounded by a close mass, more than a quarter of an inch thick, in which are ten round spots of metal; in other words, the sectional ends of rod iron wires. In fact, the protecting mass will be found to consist of ten closely-twisted strands of the soaked Manilla yarn, each strand having iron wire in the middle. It is at the separate factory, then, some hundreds of yards from the closing and coiling machinery at Morden Wharf, that this covering is manufactured, 50 tons of the iron wire being used every week, in combination with Manilla yarn at the rate of 6½ tons a day. The wire is received in coils from Birmingham, and, having been oiled, is stored until wanted; then it is joined very carefully by scarfed ends, or ends cut transversely and fitted together. The machinery by which the Manilla yarn is twisted round the wire is very ingenious, each machine being a long horizontal shaft or spindle, with alternate discs of perforated iron and bobbins of the gold-coloured yarn. In one set of machines the axis of the bobbins is parallel to or identical with the spindle, and the revolution is the same in rapidity as the fixed iron discs; but in an improved series of mechanism above stairs this arrangement is altered, the bobbins being set transversely with the shaft, and revolving very much more slowly. It is, indeed, a curious and rather perplexing sight to observe the difference in the two motions, the discs whirling so rapidly as to render almost invisible the threads of yarn passed eccentrically through the holes, while each thread unwinds itself in the coolest and most leisurely way from the bobbin. These machines will turn out 140 miles of Manilla-covered wire in a day. As it is twisted it goes through the hot solution above-mentioned, and it is then passed through a trough of water to cool it. These little details must be noted by the visitor by use of his own eyes; for during the time of his being inside this factory his power of distinguishing the sounds of the human voice, even ~~if conveyed in a shout~~, is in abeyance. The noise of the machinery is, indeed, absolutely deafening, its effect on the drum of the ear being felt for a minute or two after any person unaccustomed to such enormous and indescribable din has left the building.

At the Morden Wharf factory another stage of operations is commenced. Here the core is received on large reels, and is sunk in circular openings, which are then filled up with water. From first to last, we may here observe, the cable is in all its processes of formation at this factory kept in water, that any flaw in the coating may the more quickly be made apparent. For twelve hours the coils of core are subjected to electrical tests, their continuity being ascertained and their complete isolation proved beyond a doubt. Malicious injury to the core in its transit from the Gutta-percha Works to Morden Wharf would thus be defeated in its purpose by prompt detection and remedy. The joining of the ends is, we need hardly say, about the most delicate operation in the whole course of manufacturing the Atlantic or any telegraphic cable; and whenever the electrician proclaims a faulty transmission of the current, the chances are a hundred to one that the flaw will be found in one of the joints.

Before being worked into cable with the ten strands of wire and yarn, the core is wrapped in a twisted fold of jute, which may be just distinguishable in one of those sections that we have already alluded to, and which are in some request as souvenirs. The machinery by which the cable is twined occupies two floors. The closing machines are below, and they consist of large wheels or tables, revolving horizontally, with reels of the several strands so arranged on their margins as to maintain a relatively stationary position, instead of always keeping their axes pointed to the centre of motion. The strands, converging upward towards a small opening in the roof, meet, and are twisted round the jute-covered core, and so form the entire cable, which is conducted over grooved wheels to another and very noteworthy department. A visit to a large brewery is recalled by the appearance of this place, where platforms lead between huge tanks, or what would elsewhere be vats. They are eight in number, four being round and four oval. The round tanks are 34 feet in diameter, and the oval ones measure 36 feet by 27. Their depth is 12 feet, and they are intended as receptacles for the cable, which descends into them from the wheels overhead, and is coiled very neatly by manual labour. Each tank will conveniently hold 140 miles of the cable, but their capacity, if taxed to the utmost, would be found greater by some ten miles or more. A stream of water constantly falls over the edge of each tank, and, percolating the coils of cable finds its way into an open space which is kept clear in the middle, where it rises to a level with the coil. The water tests the efficiency of the protective covering; and the delicately adjusted batteries in the electrician's room, into which the ends of all the cables are led in one bunch, proves the conducting power to be uninfluenced by any penetration from without. A measured force is being continually sent through the wires, and the least defect in the insulation can thus be registered with unfailing accuracy, even to its exact distance and degree. Hitherto the superintendents of this anxious work have been very fortunate; but it has sometimes happened that a great length of cable has had to be uncoiled, the defective joint cut out, and the whole made good. An account is kept of the daily progress, and there were 629 miles completed on Friday evening, to which another 12 miles would have been added by the end of the following short day's work; so that, speaking tolerably "by the card," we may state that the number of miles of finished wire at this time in the tanks at Morden Wharf is 641. The distance from the west coast of Ireland to Trinity Bay, Newfoundland, is 1,640 nautical miles. Two of the eight tanks are nearly full, and will soon be ready for embarkation by the Amethyst and Iris, two ghostly-looking hulks, which lie alongside near the wharf. The decks of these vessels have been knocked about considerably, and in great part got rid of, to make room for tanks in which the cable will be stowed in the same manner as at the factory. The hulks, when laden, will be towed to the Medway, where the Great Eastern is now lying, with three enormous tanks on board, occupying, by comparison with the surrounding bulk, so little space as to deceive experienced eyes as to their actual dimensions. The Iris and the Amethyst have each two tanks on board, the diameter of which is somewhat less than those at Morden Wharf, the depth being greater. They will have to make nine trips to get all the cable alongside the "big ship."

Mr. Canning and Mr. Clifford, under whose control the operations have been conducted at East Greenwich, will accompany their precious charge on board the Great Eastern, and will direct the laying of the cable across the Atlantic Ocean. Our statement of the mileage of perfected cable gives but little idea of the length of all the materials taken separately. For example, to make up the 2,300 miles of cable which, allowing for various contingencies, will be required, 16,000 miles of copper wire are used. The insulating material is equal to an aggregate length of 18,400 miles; the jute, being in ten strands, will extend to 23,000 miles, which will also be the length of the iron wire; and as each wire is separately covered with five twists or strands of yarn, 135,000 miles of the latter will be worked into the cable; making together a length of material which amounts to 215,500 miles. What these figures really signify may be understood by reference to the astronomical fact that the distance of 237,000 miles is that from the earth to the moon.—*Daily Telegraph.*

CORRESPONDENCE.

PROFESSOR HUGHES'S PRINTING TELEGRAPH.

To the Editor of the TELEGRAPHIC JOURNAL.

SIR,—I notice in the last number of your journal a short account of the invention of my printing telegraph, copied from the *Telegrapher*, ascribing this invention to a "lucky accident." I am sorry to say that the article in question is without the slightest foundation of truth.

In 1850 I first commenced my printing telegraph, being at that time Professor of Natural Sciences in Kentucky, and it required three years constant experiments before the instrument was capable of transmitting a single word.

This instrument has now become of great practical value, but it has become so only by the unremitting attention and constant improvements which, unassisted, I have been able to make during the last fourteen years.

Thus accident has had but little to do in the invention and perfection of this telegraph system.

Sincerely yours,
D. E. HUGHES.

85, Rue Notre Dame des Champs,
Paris, Dec. 19, 1864.

ELECTRICITY APPLIED TO ORGANS.—Mr. Barker, organ builder, Paris, is said to be the inventor of a mode of applying electricity in the construction of organs, so that the largest organ may be played as easily as the piano, and the pipes may be distributed anywhere through a church. This invention is now being applied to a great organ in course of construction for the church of St. Augustin in Paris.

TELEGRAPHIC NEWS.

Professor Hughes's Synchronous Printing Telegraph.—The French Government have now sixty-five of these beautiful instruments in operation. They are also employed on the Italian lines of telegraph from Turin to Naples, Florence, Geneva, Milan, &c. &c.

The Pier at Southport.—This is the longest pier in England, its original length being 1,200 yards, but it has since been extended to 1,700 yards. The original 1,200 yards is traversed by a small tramway, over which carriages are drawn (for the convenience of invalids) by a stationary engine fixed midway on the pier. Electrical bells are being fixed from each end to the engine-house, so as to acquaint the engineer when to start the engine. The bells are being fixed by Mr. B. Boothroyd, of Southport, and are working excellently. The same gentleman has fitted up a number of bells at the Royal Hotel, Southport. The system used is that of M. Bréguet, as used at the Grand Hotel and Louvre at Paris. The system is in admirable working order.

Electricity and the Electric Telegraph.—On Tuesday evening, the 20th instant, a lecture was delivered on the above subject in St. Paul's Schoolroom, Southport, by Mr. William Morton, of the Magnetic Telegraph Company. The Rev. T. J. Clarke in the chair. The lecturer commenced by stating that few inventions had caused so much surprise and delight as the electric telegraph; and although it had almost become a necessity to many of us, but little was popularly known of this wondrous agent. Of the universality of electricity, it was stated that there was as much employed to combine the gases in one drop of water as would, if instantaneously liberated, cause a flash of lightning sufficient to rend the majestic oak or destroy animal life; and that, in fact, electricity was universal, and every science must be exhausted before its limits could be ascertained. The lecturer drew attention to the different arts of telegraphing used by the ancients, and particularly the aerial and semaphore systems. An electro magnet was first introduced,—it was a piece of soft iron in the shape of a horse-shoe, supported on a large wooden stand, and a battery having been attached, a 28-pound weight was held suspended as long as the current was kept on. A thin piece of wire was next attached to a small stand, and a very powerful battery attached, the wire was instantly rendered red hot, and burnt up, and an explosion of gunpowder was also shown by this experiment. The lecturer then gave a description of the component parts of the needle telegraph. He stated that the action of the needle was based upon the principle of Professor Oersted; that a magnetised needle, free to rotate on its centre, when brought near to a wire through which a current of electricity was passing, tended to place itself at right angles to that wire. This was illustrated by a large needle fixed on a stand, and also showed that by reversing the currents the needle could be made to move either to the right or left, at the desire of the operator. A small electrical engine was then exhibited and described, and it was greatly admired, as was also an electrical pump, for pumping water. The lecturer stated that it was almost impossible to state to what purposes electricity might not be applied. The gas having been turned out, the electric light was exhibited. The lecturer stated that it was qualified for lighthouse purposes, and that it was at present in use at Dungeness Lighthouse, and so powerful was it that it could be seen from the coast of France, the distance across being about thirty miles. The different instruments used in telegraphy were next described, and referred particularly to the needle instrument and the registering instrument of Professor Morse, and the bell system of Sir Charles Bright, as used by the Magnetic Telegraph Company; and in order to show the practical working of the bell system, he requested any of the audience to write down a message. Several messages were sent from one end of the room to another, eliciting applause. The lecturer then adverted to the advantage of this instrument. Pieces of submarine cables were now exhibited, and a small length of the Atlantic and other cables described, showing their different construction. The lecturer desired to call attention to the last great cable the Persian Gulf Cable, which was laid this year by Col. Stewart, Sir Charles Bright, Col. Goldsmidt, and others. By the laying of this cable it brought our communication with India to within a few hours, and that in the course of three or four years from now we might expect to have daily telegrams from Hong Kong, Melbourne, Sydney, and Adelaide. The lecturer then described in verse the different uses which were made by the public in using the telegraph. The lecture was listened to throughout with great attention. After firing a salute with a small cannon, a shocking-coil was introduced, when several of the audience joined hands together, and received a shock; this experiment caused much merriment. A vote of thanks having been given to the lecturer for his interesting lecture, and to Mr. B. Boothroyd for his kindness in assisting, the meeting separated at half-past nine o'clock.

Telegraphic Grievances.—The following is an extract from a letter which appeared in the columns of the *Times* on the 17th instant:—" Sir,—We receive on an average eight messages monthly. Those messages consist of summaries of European and American news, and cost us fully £100 per month. Latterly not one of these has reached us but in a mutilated and incoherent state, not merely an incorrect rendering of a word or words, which must at all times and places be looked for, but so carelessly and ignorantly transmitted as to necessitate the striking out frequently of sentences, and occasionally of whole paragraphs, in some instances entirely destroying the value of the entire telegram. Bad as it is to have to pay for repetition, it is infinitely worse to be shut out from it altogether, as we are in Bombay. The wire goes no further than Suez, and in whatever state a message may arrive there so it is sent on. We are no worse off than our neighbours, for we are very frequently called upon to decipher messages equally as unintelligible as our own. Our messages are compiled by Mr. Reuter, and I am assured by that gentleman every effort is used to insure correct transmission. The only way in which this scandalous business can be remedied is by employing English signallers at all the repeating stations on the continent. Until this be done it is hopeless to expect a better state of things. Occasionally messages are detained so long *en route* that they arrive at Suez after the steamer they are intended to catch has sailed. The next 'available opportunity' is the Calcutta boat, by which they are despatched to Point de Galle. A message thus sent manages to precede the next Bombay mail by a couple of days or so, of course utterly useless, the Calcutta boat bringing a week's later news. No refund can be obtained, because the messages reached Bombay quicker than the regular post! It is said the Continental lines are 'blocked' with messages. No doubt they are, and ever will be, if the present system of signalling is continued. Surely, where such vast interests are at stake, something more than suing the company might be attempted. W. Charman, Managing Proprietor of the *Bombay Gazette*."

MISCELLANEA.

British North American Provinces.—In the semi-official terms proposed for the confederation of the provinces of British North America, we are glad to find that the working of the telegraphic system will be left to private enterprise.

Electro-plating by Magneto-electric Machines.—In America several large firms have abandoned the use of magneto-electric machines for electro-plating, and resumed the use of batteries. Mr. Beardslee, of College Point, continues the use of the machines referred to, and considers the cost of steam power for these machines less than that of acids and metals for batteries to do the same work.

THE SONG OF ELECTRICITY.

I am the spirit of light and love;
 To my unseen hand 'tis given
To pencil the radiant clouds above,
 And polish the stars of heav'n.
I scatter the golden rays of fire
 On the horizon far below;
And I deck the skies, where storms expire,
 With a red and dazzling glow.

My being is like a simple thought
 That dwells in a sinless breast;
A tone of music that ne'er was caught,
 A word that was ne'er expressed.
I burn in the bright and burnished halls,
 Where the fountains of sunlight play,
Where the curtain of gold and opal falls
 O'er the scene of the dying day.

Away! away! through the viewless air,
 Stretch forth your iron thread,
For I will not dim my sandals fair,
 With the dust ye tamely tread.
Aye! rear it up on its million piers,
 Let it reach the world around;
And the journey ye make in a hundred years,
 I'll clear at a single bound.—*The Telegrapher*

PRICES CURRENT OF INSULATING MATERIAL.

Gutta Percha, as imported.

Genuine, fine and good	1/9 to 2/	per lb.
India Rubber.		
Para, first quality	1/8 to 1/9	"
second "	1/4 to 1/5	"
third Negro-head	1/2	"
Java and Penang	1/2 to 1/4	"

Wm. Kirkmann, 4, *Howford-buildings, Fenchurch-street.*
